Hemolytic anemia is detected in the majority of the patients, and the spleen is almost always enlarged.

### Laboratory Findings

The anemia is normocytic and normochromic and tends to be mild in degree. Severe anemia requiring blood transfusions<sup>5</sup> is unusual. The anemia results from excessive red cell destruction, but the intensity of hemolysis varies considerably from one patient to another and in the same patient at different times. When moderate to severe, it is accompanied by reticulocytosis, erythroid hyperplasia of the marrow, increased excretion of bile pigments, and reduced values for erythrocyte life span.<sup>17,20</sup> Ineffective erythropoiesis may be prominent, as manifested by a pronounced increase in "early-labeled" bile pigments (Chapter 5).<sup>15</sup>

The most characteristic metabolic abnormality is greatly increased urinary excretion of uroporphyrin I, a biologically useless isomer that cannot be converted to heme. Increased urinary excretion of uroporphyrin III<sup>24</sup> and coproporphyrin I may also occur, but to a lesser extent than that of uroporphyrin I. Trace quantities of porphyrins with 7, 6, 5, and 3 carboxyl groups also may be

Fig 32-1. Patterns of porphyrin and precursor excretion in six types of porphyria. The pathway of heme biosynthesis is shown at the top of the figure. The major intermediates excreted in each type of porphyria are indicated by the shadow areas below the appropriate intermediate. ALA = delta aminolevulinic acid. PBG = porphobilinogen. URO = uroporphyrin. COPRO = coproporphyrin. PROTO = protoporphyrin. Each of the biosynthetic enzymes is numbered: (1) ALA synthetase (ALA-S), (2) ALA dehydratase (ALA-O), (3) uroporphyrinogen I synthetase (US), (4) uroporphyrinogen III cosynthetase (UC), (5) uroporphyrinogen decarboxylase (UD), (6) coproporphyrinogen oxidase (CO), (7) heme synthetase (HS).

detected in the urine.<sup>18</sup> Fecal excretion of porphyrins, especially coproporphyrin I, is increased<sup>1,2,12</sup>; uroporphyrin I is greatly increased in erythrocytes<sup>1,20</sup> and in plasma.<sup>1</sup>

#### Nature of the Metabolic Abnormality

Studies with fluorescence microscopy suggest that the excess porphyrins are formed in red cell precursors.<sup>20,23</sup> When bone marrow is examined in this way, there appear to be two populations of normoblasts, one normal and one in which excessive amounts of porphyrin are present, especially in the area about the nucleus. The abnormal population is further characterized by nuclear inclusions,<sup>6,9</sup> probably containing hemoglobin,<sup>20</sup> and by excessive cytoplasmic iron granules.<sup>23</sup>

Studies of the porphyrin biosynthetic pathway in erythrocytes, as well as in skin fibroblasts, show that the activity of uroporphyrinogen III cosynthetase (uroporphyrinogen isomerase) is severely impaired (Fig. 32-1, reaction 4).<sup>19</sup> Furthermore, levels of this enzyme in heterozygotes are intermediate between those present in homozygous patients and those in normal subjects. It is reasonable to conclude that lack of this enzyme constitutes the primary genetic abnormality; as a result, much of the porphobilinogen normally utilized for uroporphyrinogen III synthesis is converted instead to uroporphyrinogen I, a compound which, being unutilizable, must be excreted. However, this formulation would not easily account for the occasionally observed increase in uroporphyrin III excre-

Table 32-2. Genetic and Metabolic Abnormalities in the Porphyrrias

tion nor for the lack of an overall deficiency of heme production. An alternative, less plausible hypothesis holds that the primary genetic defect leads to production of δ-aminolevulinic acid (Fig. 32-1, reaction 1) in such large amounts that the capacity of subsequent enzymes to convert it to uroporphyrinogen III is exceeded.<sup>24</sup>

### Treatment

Splenectomy may partially or completely relieve the hemolytic anemia<sup>3</sup> and may also lead to reduced porphyrinuria and photosensitivity.<sup>1,23</sup> Furthermore, hypertransfusion to suppress erythropoiesis decreases porphyrin excretion.<sup>8</sup> However, splenectomy is not always necessary and hypertransfusion is not a practical long-term therapeutic device. Most patients rely on avoidance of exposure to sunlight. They should be instructed to wear special protective clothing, including gloves and broad-brimmed hats, to cover all

possible cutaneous surfaces. Conventional sun-screening agents and sunburn preventatives are ineffective since they screen out wavelengths less than 300 nm. The active wavelength with respect to porphyrins is about 400 nm,<sup>16</sup> which is near the visible range. Thus, to be effective, a local agent must be visible on the skin. Reflective materials such as zinc oxide or titanium dioxide are useful, as is ordinary pigmented theatrical makeup.<sup>16</sup> Preparations containing substituted quinones (eg, lawsone) and dihydroxyacetone turn the skin a cosmetically acceptable brownish-tan and may also be effective.<sup>4,22</sup>

### Congenital Porphyria in Animals

Congenital porphyria ("pink-tooth") in cattle appears to be very similar if not identical to the human disorder. In cattle, the disease is inherited as an autosomal recessive trait. Photosensitivity of skin areas not covered by pigmented hair as well as hemolytic anemia have been observed. The teeth and bones are stained red. Uroporphyrin I and smaller amounts of coproporphyrin I are excreted in the urine. Furthermore, uroporphyrinogen cosynthetase activity is severely impaired in erythrocytes.<sup>19</sup> A similar disorder has been observed in pigs, but the inheritance pattern appears to be dominant.<sup>10</sup> In the fox squirrel (*Sciurus niger*), little uroporphyrinogen III synthetase is found, and the excretion and tissue deposition of uroporphyrin I are similar to those in congenital erythropoietic porphyria, but this species seems to suffer no ill effects.<sup>14</sup>

## Acute Intermittent Porphyria

### (Pyrroloporphyria, Swedish Porphyria)

Acute intermittent porphyria is a disorder in which delta-aminolevulinic acid (ALA) and porphobilinogen (PBG) are produced in excess by the liver and are excreted in the urine. This metabolic abnormality is accompanied by acute attacks of mental, abdominal, and neurologic symptoms. Although patients

with acute intermittent porphyria probably were reported by Gunther,<sup>7</sup> it was the extensive family studies made in Sweden by Waldenstrom that provided the first comprehensive descriptions.<sup>71</sup>

### Genetics and Prevalence

Inherited as an autosomal dominant trait,<sup>22,67,72</sup> this type of porphyria is relatively common. The overall prevalence has been estimated at 1.5 per 100,000 population,<sup>44</sup> but in some areas a much greater prevalence has been noted, for example, in Lapland (1:1000)<sup>44</sup> and in Sweden (1:13,000).<sup>76</sup> Not only is this disorder more common in women (60 to 75% of patients) than in men, but the frequency and severity of attacks are also considerably greater in women.<sup>22,67,72</sup> The onset of the disease usually occurs in late puberty or early adulthood, but may occur later in men (average age, 36 years) than in women (average age, 25 years).<sup>67</sup>

### Clinical Description

The clinical course is marked by recurrent, acute attacks lasting several days to several months. These are interspersed with long and variable asymptomatic or latent periods. There may be as few as three attacks in a lifetime or as many as two or three per year.<sup>67</sup> Acute attacks may be precipitated by exposure to certain drugs, barbiturates and sulfonamides being the most common but many others have also been implicated (Table 32-3). In some women, attacks occur just prior to the menstrual period. Other precipitating factors include decreased food intake,<sup>53,77</sup> infection, and alcohol excess. In about 25% of attacks, the precipitating factors are unknown.<sup>67</sup> Endogenous steroid metabolites having the 5 $\beta$ -H configuration may play a role in precipitating some of these attacks.<sup>46,47,52</sup>

Acute porphyric episodes are characterized by a triad of abdominal, neurologic, and mental symptoms. The most common one is abdominal pain, occurring in about 95% of

**Table 32-3. Drugs and Toxins Which May Precipitate Acute Attacks in Acute Intermittent Porphyrria, Variegata Porphyrria, or Coproporphyrria<sup>22,36</sup>**

<i>Evidence for Porphyrrogenic Effect</i>

\*Agents used to induce experimental porphyrria in animals

the patients.<sup>67</sup> The pain is usually described as moderate to severe in degree and as crampy or colicky in nature. It may be generalized or periumbilical, or located predominantly in the lower quadrants. It is characteristically accompanied by constipation and, often, by vomiting. Because these symptoms have mistakenly been attributed to a variety of conditions requiring emergency operations, many of the patients have been subjected to unnecessary laparotomy. Dilated bowel loops may be palpable, but the abdo-

men usually is soft, and there is no rebound tenderness or other sign of peritoneal irritation.

The patients often complain of pain or paresthesias in the extremities, but motor symptoms usually are the dominant sign of peripheral neuropathy. There may be mild to moderate weakness in one or more extremities and these manifestations may progress to flaccid quadriplegia. In one series, 11 of 35 patients developed quadriplegia and 10 others had less generalized motor symp-

toms.<sup>67</sup> Paralysis of respiration, the most serious manifestation of the neuropathy, is less common. It may be so severe that mechanical assistance is required.<sup>42</sup> Other relatively less common neurologic manifestations include the "restless legs" syndrome,<sup>49</sup> and impaired function of the facial, extraocular, trigeminal, and other cranial nerves. Deep tendon reflexes commonly are absent. Frequently there are tachycardia,<sup>64</sup> hypertension, postural hypotension, inappropriate sweating, and bladder distension, findings which are thought to be manifestations of autonomic neuropathy.

Mental symptoms resemble a toxic delirium and include hallucinations, confusion, and acute anxiety states.<sup>33,61</sup> Some of these symptoms may be a manifestation of hyponatremia (page 1028). Occasionally, manic-depressive or schizophrenic behavior is observed.<sup>22,33</sup> Tonic-clonic seizures were observed in 20% of patients in one series.<sup>67</sup> Depression, including suicidal tendencies, may follow an attack.

### Laboratory Findings

Results of routine hematologic measurements usually are within normal limits; however, leukocytosis occasionally is observed during acute attacks,<sup>67</sup> and this finding may support an erroneous impression of an abdominal condition requiring an emergency operation. In one series, four patients with iron-deficiency anemia and two with unexplained, normocytic, normochromic anemia were found among 46 patients with the disease.<sup>67</sup> More frequently, the red cell mass is reduced even though the VPRC is normal.<sup>31</sup> Red cell survival is normal, suggesting that the decreased red cell mass results from reduced effective erythropoiesis.<sup>31</sup>

The characteristic abnormality of porphyrin metabolism is the excessive urinary excretion of PBG and, to a lesser extent, ALA. These porphyrin precursors can be quantified accurately by means of a chromatographic method.<sup>56</sup> Normally, less than 3 mg of either ALA or PBG are excreted in 24 hours. In

21 symptomatic patients, an average of 83 mg of PBG per 24 hours (range 30 to 200) and 43 mg of ALA per 24 hours (range 8 to 150) were excreted.<sup>67</sup> ALA and PBG excretion tends to decrease somewhat during remission. In 12 asymptomatic patients, the average urinary PBG was 32 mg/24 hours (range 12 to 60) and ALA was 10 mg/24 hours (range 6 to 18).<sup>67</sup> In exceptional patients, values fall into the normal range during latent periods.<sup>22,55</sup>

Urinary PBG also may be detected by a qualitative method, the Watson-Schwartz test.<sup>72</sup> This test yields negative results in normal subjects and positive ones when PBG exceeds about 6 to 8 mg/24 hours.<sup>22</sup> When properly performed and interpreted, the Watson-Schwartz test may be relied upon. However, in routine laboratories, falsely positive results are common. In the experience of one referral center, 75% of patients with supposedly positive findings had normal values when the chromatographic method was used.<sup>67</sup> Urobilinogen, indoles, and certain indicator dyes such as pyridium, methyl red, skatol red, and melanogens may be excreted in the urine and confused with PBG in the Watson-Schwartz test. The precautions necessary to ensure proper interpretation of the results of the test have been outlined by Watson and his co-workers.<sup>22,74</sup>

Because PBG is a colorless substance, freshly excreted urine from patients with acute intermittent porphyria often appears normal in color. On exposure to light and air, especially at alkaline pH, PBG-containing urine darkens. The phenomenon is largely accounted for by the formation of porphobilin, a dark-brown, non-porphyrin oxidation product of PBG.<sup>73</sup> In addition, PBG may be converted nonenzymatically to a mixture of porphyrins, especially uroporphyrins.<sup>34</sup> Thus, under certain conditions, urine porphyrins may appear to be increased in persons with acute intermittent porphyria, but this finding is largely artifactual.

Fecal porphyrins may be slightly to moderately increased, but not to the degree found in association with variegate porphyria or coproporphyria.<sup>17,35,48</sup>

Hyponatremia, reduced blood volume, and mild elevation of blood urea nitrogen frequently are observed during acute attacks.<sup>67</sup> Often these findings can be attributed to sodium loss by vomiting. However, in a number of instances, the syndrome of inappropriate antidiuretic hormone secretion has been documented,<sup>50,54,67</sup> presumably owing to hypothalamic involvement. When carefully searched for, other evidence of hypothalamic abnormality has been found, such as disturbed regulation of growth hormone and ACTH secretion.<sup>62,75</sup> The serum protein-bound iodine often is increased, but this usually results from elevated levels of thyroxine-binding globulin rather than from hyperthyroidism.<sup>67</sup>

The results of liver function tests usually are within normal limits except for those of the Bromsulphalein (BSP) retention test. More than 10% of administered BSP was retained in 79% of symptomatic patients and in 55% of those in remission.<sup>67</sup> This abnormality appears to be due to a functional defect in the conjugation and excretion of BSP<sup>66</sup> and is not accompanied by structural abnormalities as shown by liver biopsy.<sup>51</sup>

Abnormal electroencephalographic (EEG) patterns are the most common laboratory signs of neurologic disease. Diffuse, nonspecific slowing of the wave pattern was found in 14 of 24 patients during an acute attack.<sup>67</sup> This abnormality tended to disappear when remission occurred. Less commonly, focal EEG abnormalities may be found in the absence of local neurologic disease. The cerebrospinal fluid usually is normal, but the protein concentration occasionally is slightly increased. In patients with neuropathy, the electromyogram may demonstrate a denervation pattern and denervation atrophy may be found on muscle biopsy.

Abdominal x rays may demonstrate distended bowel loops in patients with abdominal pain. Impaired glucose utilization is common during acute attacks; the fasting blood sugar value was usually normal, but the results of the glucose tolerance test were abnormal in 11 of 15 patients.<sup>67</sup> Hypercholesterolemia is common.<sup>69</sup>

## Nature of the Metabolic Abnormality

The activity of ALA synthetase (Fig. 32-1, reaction 1) is distinctly increased in liver tissue from patients with acute intermittent porphyria.<sup>70</sup> This observation led to the suggestion that the primary genetic defect is a constitutive operator mutation leading to overproduction of this enzyme. Although such a defect could account for excessive production of ALA and PBG, it does not explain why these precursors are not converted to porphyrins. In normal subjects, a significant fraction of administered ALA is excreted as porphyrins.<sup>37</sup> Furthermore, in patients with variegate porphyria (page 1029) an increase in ALA synthetase activity leads to excretion of several porphyrins in addition to ALA and PBG (Fig. 32-1). Accordingly, it has been suggested that the increased ALA synthetase found in patients with acute intermittent porphyria is a compensatory phenomenon, occurring as a result of a block elsewhere in the heme biosynthetic pathway. Such an increase would be consistent with a reduced effect of the known feedback inhibition and repression control exerted by heme on ALA synthetase activity (page 169). A logical site for the primary block in acute intermittent porphyria is at the step catalyzed by the enzyme uroporphyrinogen synthetase (Fig. 32-1, reaction 3), in which porphobilinogen is converted to porphyrins. Indeed, reduced levels of this enzyme were demonstrated in the liver<sup>58,63</sup> and erythrocytes<sup>57</sup> of patients with acute intermittent porphyria. Furthermore, subjects with latent disease could be detected by assay of this enzyme at a time when urinary excretion of ALA and PBG was normal.<sup>37</sup> Thus, reduced uroporphyrinogen synthetase activity, inherited as an autosomal dominant, appears to be the most likely primary genetic defect in this form of porphyria. The increase in ALA production may serve a compensatory function, making possible the synthesis of heme at a normal rate. Exogenous or endogenous factors which lead to further increases in ALA production, however, may precipitate acute attacks. These factors include drugs

(Table 32-3) as well as certain steroid metabolites.<sup>46,47,52</sup> The influence of the latter may account for the typical onset of the disease at puberty as well as the relation of acute attacks to events in the menstrual cycle of some women.

The relation between the metabolic abnormality and the symptoms remains a mystery. It seems reasonable to propose that PBG or a derivative is toxic to the nervous system. Indeed, PBG and porphobilin have been shown to inhibit neuromuscular transmission under experimental conditions.<sup>39</sup> On the other hand, it has not been possible to induce neurologic abnormalities by administering PBG to animals,<sup>43</sup> normal human subjects,<sup>37</sup> or even patients with latent porphyria.<sup>57</sup> Furthermore, there is at best only a partial correlation between the neurologic symptoms and urinary or plasma PBG levels.<sup>53</sup>

### Treatment and Prognosis

Prevention of acute attacks by avoiding exposure to toxins, especially barbiturates, is most important. Patients should be given a list of drugs to avoid (Table 32-3) and should carry it with them at all times. A high-protein, high-carbohydrate, low-fat diet should be maintained,<sup>22</sup> and the patients should be warned that fasting may induce attacks.<sup>53</sup> They should also know that maintenance of the diet is important enough to require the attention of a physician whenever adequate oral intake is interfered with by intercurrent disease. In women whose attacks are related to the menstrual cycle, prevention can be achieved by suppression of ovulation with androgens or estrogen-progesterone contraceptive pills.<sup>61,67</sup>

When an acute attack occurs, hospitalization usually is required. A primary goal of therapy, based on the repression of ALA synthetase by glucose,<sup>77</sup> is to administer calories in the form of carbohydrate and protein. At least 300 g of glucose should be given in the first 24 hours. If oral intake is possible, glucose may be given in fruit juice by mouth. If necessary, 10% glucose or fructose solutions may be administered intravenously.<sup>22</sup> In

patients with carbohydrate intolerance, insulin may be required.<sup>22</sup> With high carbohydrate administration, a pronounced decrease in urinary porphobilinogen was observed in 13 of 16 patients, and the acute attack was aborted in 10 of 14 patients with symptoms.<sup>67</sup> However, these data must be interpreted with caution, for spontaneous recovery may occur, and, as yet, carefully controlled studies have not been possible.

Phenothiazines are useful in symptomatic therapy.<sup>22,59</sup> Chlorpromazine may be given in doses of 25 mg or more four times a day. This may control pain as well as mental symptoms. Opiates may be employed if pain is severe. Lithium carbonate may be useful in treating depression.<sup>67</sup>

Preparation for artificial support of respiration should be made if neuropathy is progressive. Adequate respiratory care in the paralyzed patient can be life-saving.

Possible therapeutic benefit in acute intermittent porphyria has been attributed to adenosine monophosphate,<sup>41</sup> chelating agents,<sup>63</sup> zinc,<sup>65</sup> hematin,<sup>32</sup> vitamin E,<sup>60</sup> and deoxypyridoxine.<sup>38</sup> None of these modes of therapy has become established, and further investigation is required before their use can be recommended.

The acute attack of porphyria may be fatal. A mortality rate of 24% over a five-year period was reported in one series of 50 patients.<sup>43</sup> In another, more recent series, four fatalities were recorded among 46 patients.<sup>67</sup> Death usually results from the consequences of respiratory paralysis or from cardiac arrhythmias secondary to sympathetic discharge. The mortality rate appears to be decreasing,<sup>72</sup> probably because of earlier case-finding coupled with the prohibition of barbiturates and other toxic drugs.

### Variegate Porphyria

(Mixed Porphyria, Protocoproporphyria, Porphyria Cutanea Tarda Hereditaria, South African Genetic Porphyria)

Variegate porphyria is a disorder in which large amounts of protoporphyrin and copro-

porphyrin are excreted in the feces. Like acute intermittent porphyria, the disease is marked by the occurrence of acute attacks that are accompanied by excessive urinary excretion of PBG and ALA and are often precipitated by ingestion of barbiturates. In

addition, however, variegate porphyria is characterized by photosensitive cutaneous manifestations.

Although Gunther<sup>7</sup> and Waldenström<sup>71</sup> recognized cases of porphyria in which neurologic and cutaneous manifestations oc-

**Fig 32-3** Cutaneous manifestations of variegate porphyria. **A**, Bulla on index finger, pigmented scars, and collapsed blisters at finger tips in a 27 year old woman. **B**, Hands of a 36 year old man, note the erosions on backs of hands, the depigmented scars of past lesions, and the subungual involvement (Photographs kindly supplied by Lennox Eales, University of Cape Town, South Africa)

curred together, it was the extensive investigations of Dean and Barnes in South Africa that provided the most complete information about this disease and clearly distinguished it from acute intermittent porphyria.<sup>81</sup> Indirect evidence suggests that George III and other members of the royal houses of Stuart, Hanover, and Prussia may have suffered from this form of porphyria.<sup>93</sup>

### Genetics and Prevalence

Variegate porphyria is inherited as an autosomal dominant trait. The studies in South Africa identified at least 236 patients in 13 families, all of whom trace their lineage to a single couple who migrated from Holland in 1688.<sup>81</sup> Among the white (Afrikaner) population of South Africa, there are an estimated 12,000 persons with variegate porphyria in a population of 3,000,000, a prevalence of 1:250. The illness is also seen in the "Cape Coloured" race in Capetown, South Africa, but not in the Bantu.<sup>86</sup> It is considerably less common outside of South Africa; however, families with a similar or identical illness have been reported from Sweden,<sup>81</sup> Holland,<sup>87</sup> Great Britain,<sup>83</sup> Denmark,<sup>93</sup> Taiwan,<sup>88</sup> and the United States.<sup>22,82</sup> The symptoms first appear in late puberty or early adult life.

### Clinical Description

In general, cutaneous manifestations tend to predominate in males whereas acute neurologic episodes are more frequent in females. This difference may result from the relatively greater use of drugs by women and a greater exposure to sun by men, rather than from an inherent difference in the disease in the two sexes.

Skin lesions<sup>16,86</sup> are the only manifestations of the disease in about half of the affected individuals. The lesions are limited to exposed areas, especially the face and hands (Fig. 32-3). Trivial mechanical trauma to these areas results in the formation of bullae, 2 to 30 mm in diameter. The bullous fluid usually is serous or blood-tinged and not

particularly rich in porphyrins.<sup>16</sup> The bullous lesions tend to rupture, often become secondarily infected, and form shallow ulcers which heal slowly and leave scars. In addition to these lesions, exposure to the sun may be followed by an acute reaction manifested by erythema and edema. Facial hirsutism and hyperpigmentation of exposed areas are common findings.

The clinical manifestations of the acute attack of variegate porphyria do not differ in any important respect from those of acute intermittent porphyria (page 1025). However, such attacks are probably somewhat less common in variegate porphyria than in intermittent porphyria and almost always occur after exposure to a known porphyrogenic drug (Table 32-3).<sup>87</sup> Mortality during an attack approaches 25%.<sup>87</sup>

### Laboratory Findings

The most characteristic and consistent abnormality in porphyrin metabolism is an increase in fecal coproporphyrin and protoporphyrin. Fecal coproporphyrin ranges from 70 to over 1000  $\mu\text{g/g}$  dry weight (normal < 100  $\mu\text{g/g}$ ).<sup>84,140</sup> Fecal uroporphyrins may also be increased.<sup>96</sup> In addition, these patients excrete excessive amounts of a hydrophilic, dicarboxylic porphyrin conjugated with a peptide ("X-porphyrin").<sup>93</sup> These abnormalities are present even when the patient has no symptoms.

During acute attacks, ALA and PBG appear in the urine. However, in contrast to acute intermittent porphyria, urinary ALA and PBG levels frequently return to normal a few weeks after the onset of an attack, even though neurologic manifestations continue.<sup>88</sup> Furthermore, urine ALA and PBG levels are characteristically normal or only slightly increased in patients whose only manifestations are cutaneous.<sup>84,86</sup>

### Nature of the Metabolic Abnormality

As in acute intermittent porphyria, ALA synthetase activity is increased in the liver (Fig. 32-1, reaction 1).<sup>85,94</sup> This may be the

only abnormality, since the pattern of porphyrin excretion is similar to that in normal subjects given ALA.<sup>37</sup> (See discussion, page 1028.)

### Treatment

Acute attacks should be prevented and treated as outlined for acute intermittent porphyria. Since the "glucose effect" (page 1029) has been shown to operate in variegate porphyria,<sup>91</sup> a high-carbohydrate, high-protein diet is also advised for these patients.

In addition, subjects with cutaneous manifestations should be instructed to avoid sun exposure. The measures and topical agents described in connection with congenital erythropoietic porphyria (page 1025) may be useful for these patients.

## Hereditary Coproporphyria

This form of porphyria is characterized by the continuous, excessive fecal excretion of coproporphyrin III. Protoporphyrin excretion remains normal or only slightly increased.

The first comprehensive description of the disorder was that of Berger and Goldberg.<sup>81</sup> Since then, more than 40 cases have been reported.<sup>89,90</sup> The disease resembles acute intermittent porphyria and variegate porphyria in several important respects: (1) it is inherited as an autosomal dominant trait; (2) the excessive porphyrins are formed in the liver, probably because of excessive ALA synthetase activity<sup>92</sup>; (3) acute attacks occur which may be precipitated by barbiturates, anticonvulsants, sedatives (Table 32-3), and, unlike acute intermittent and variegate porphyria, chlorpromazine.<sup>89</sup> During these attacks ALA and PBG are excreted into the urine.

Over 60% of the patients with hereditary coproporphyria have no symptoms.<sup>89,90</sup> Most of the remainder complain of intermittent attacks, often beginning in childhood, that are similar to those seen in patients with acute intermittent porphyria. Photosensitivity has been observed but is less common than in

variegated porphyria. Fecal coproporphyrin is increased to between 100 and 3000  $\mu\text{g/g}$  dry weight (normal  $<40 \mu\text{g/g}$ ), but fecal protoporphyrin is normal or only slightly increased. Urine coproporphyrin may also be increased during symptomatic periods but usually is normal during remissions.

The primary genetic lesion is not completely understood. It has been suggested that there may be a partial block in the conversion of coproporphyrin to protoporphyrin<sup>17</sup> (Fig. 32-1, reaction 6), but this reaction has not been measured directly. Another hypothesis holds that the illness results from a mitochondrial defect that impairs uptake of coproporphyrinogen for subsequent incorporation into heme.<sup>90</sup>

Hereditary coproporphyria should be managed as outlined under acute intermittent porphyria.

## Protoporphyria

This inherited illness is characterized by greatly increased levels of free protoporphyrin in erythrocytes and feces. It was first described in 1961 by Magnus and coworkers.<sup>114</sup>

### Prevalence

Although accurate incidence figures are not available, protoporphyria appears to be relatively common. In the five-year period following the initial description, 65 cases were reported.<sup>103</sup> It appears to be inherited as an autosomal dominant trait<sup>107,122</sup>; however, many of the carriers have no clinical manifestations. In a study of nine families, there were 16 clinically affected individuals and 43 asymptomatic carriers.<sup>122</sup> For reasons which are not clear, protoporphyria is about twice as common in males as in females.<sup>103,104,122</sup> The disease usually is first manifested in childhood or adolescence.<sup>16,17</sup>

### Clinical Description

Patients with protoporphyria complain of a variety of cutaneous manifestations of

photosensitivity. In general, these are quite unlike those seen in patients with other porphyrias; bullae, scarring, sensitivity to trauma, hirsutism, and hyperpigmentation are uncommon. In some patients, the symptoms are subjective only.<sup>106</sup> After exposure to the sun, even through window glass,<sup>112,119</sup> for periods of a few minutes up to several hours, the patient notes intensely unpleasant sensations (photoparesthesias) such as prickling, itching, or burning. These sensations may persist for one to 24 hours, rarely as long as a week, and are partially relieved by cooling the skin.<sup>16</sup> In most patients, objective changes occur as well. Erythema resembling ordinary sunburn often appears during or shortly after exposure. Diffuse edema may develop two to three hours later. Less commonly, solar urticaria, a confluent, hive-like rash, occurs within minutes of exposure and lasts about one-half hour.<sup>114</sup> In an occasional patient, these early reactions are followed within a day or two by vesicular, eczematous lesions (solar eczema) which become crusted and last for several weeks.<sup>121</sup> Fine facial scarring and an appearance of premature aging may be seen in adults.<sup>122</sup> The cutaneous manifestations of protoporphyria do not differ greatly from those found in patients with photosensitivity of unknown cause (so-called "polymorphic light eruptions"), which is much more common and is not associated with abnormal porphyrin metabolism.<sup>119</sup>

Acute attacks of neurologic and abdominal symptoms do not occur in protoporphyric patients. The only non-cutaneous manifestations affect the hepatobiliary system. There is a tendency to develop cholelithiasis early in life,<sup>104,105,112</sup> the gallstones perhaps forming around a core of precipitated protoporphyrin. Fatal liver failure with a hepatitis-like picture or micronodular cirrhosis has been observed in several patients.<sup>101,108,125</sup> In these individuals, massive hepatic deposits of protoporphyrin were found.

### Laboratory Findings

In most of the reported patients with protoporphyria, there have been no quantitative or

morphologic abnormalities of the blood. In a patient with atypical findings, hemolytic anemia was detected and was relieved by splenectomy.<sup>118</sup>

The free erythrocyte protoporphyrin (FEP) level is greatly increased in symptomatic patients. Reported values range from 300 to 4500  $\mu\text{g}/\text{dl}$  (normal, less than 50  $\mu\text{g}/\text{dl}$ ).<sup>117,112,122</sup> Increased values for FEP may be observed in certain other conditions (Chapter 16), especially iron-deficiency anemia, but only rarely do they exceed 300  $\mu\text{g}/\text{dl}$ . In lead poisoning, however, FEP may be as high as in protoporphyria.<sup>117</sup> The FEP in asymptomatic carriers of protoporphyria ranges from normal levels to 200  $\mu\text{g}/\text{dl}$ .<sup>117,112,122</sup> In protoporphyria, the excessive erythrocyte protoporphyrin is not found in all the red cells. When examined with the fluorescence microscope, 7 to 60% of all the erythrocytes fluoresce brilliantly with the characteristic salmon-pink color of porphyrins. The remaining, non-fluorescent cells probably contain nearly normal concentrations of protoporphyrin.<sup>111</sup> In asymptomatic carriers, a small population of "fluorescytes" may be detected even when the total FEP level is normal.<sup>122,126</sup> The high concentration of porphyrin in individual erythrocytes renders them sensitive to hemolysis when exposed *in vitro* to 400 nm wavelength irradiation (photohemolysis).<sup>110,111</sup> This phenomenon probably results from lipid peroxidation at the red cell membrane.

Fecal protoporphyrin levels usually, but not always, are increased in symptomatic patients. Values usually range from 30 to 300  $\mu\text{g}/\text{g}$  (dry weight),<sup>112</sup> but may occasionally be as high as 1400  $\mu\text{g}/\text{g}$  (normal, less than 100  $\mu\text{g}/\text{g}$ ).<sup>104,107</sup> In some carriers, fecal porphyrins are elevated even when erythrocyte porphyrins are normal.<sup>107</sup> The fecal porphyrin excretion fluctuates considerably from one time period to another in the same patient,<sup>104</sup> and may be related to protein and carbohydrate intake ("glucose effect"). Following a period of fasting, an abrupt, pronounced increase in fecal protoporphyrin was observed in a study of a single patient.<sup>120</sup> Plasma protoporphyrin levels also may be increased.<sup>117</sup>

## Pathogenesis

Because of the original demonstration of protoporphyrin in erythrocytes, it was initially believed that the pigment is formed only in the erythropoietic system.<sup>114</sup> Kinetic and morphologic studies have suggested to some investigators that other organs, especially the liver, may also produce excess amounts of protoporphyrin,<sup>104,109,123</sup> but similar studies by others were considered to be consistent with the view that erythropoietic tissue is the sole source.<sup>124</sup>

The nature of the primary genetic defect in heme synthesis remains unknown. It is tempting to implicate a defect in the conversion of protoporphyrin to heme (the heme synthetase or ferrochelatase reaction, Fig. 32-1, reaction 7). Such a defect was looked for and not found in one patient,<sup>118</sup> but indirect evidence for a relative deficiency in this reaction was reported in another study.<sup>121</sup> ALA synthetase activity (Fig. 32-1, reaction 1) has been found to be increased in the plasma,<sup>118</sup> liver,<sup>104,115</sup> and blood.<sup>121</sup> The observed "glucose effect" also suggests that increased ALA synthetase activity plays a role in the pathogenesis of the disease.<sup>120</sup> However, as in patients with acute intermittent porphyria (page 1028), increased ALA synthetase activity may be a secondary rather than the primary abnormality.

## Treatment

Induction of carotenemia is effective in reducing the photosensitivity in protoporphyrin.<sup>113</sup> This may be accomplished by administration of  $\beta$ -carotene beads,<sup>113</sup> 15 to 180 mg/day, or of foods rich in carotenes, such as carrot juice.<sup>102</sup> In 29 of 30 patients so treated, sun tolerance was prolonged from less than 30 minutes to five to eight hours or more.

Since the "glucose effect" has been demonstrated in persons having erythropoietic porphyria,<sup>120</sup> it is possible that long-term administration of high-protein, high-carbohydrate diets might bring about reduction in FEP levels, but experience with such a regimen has not yet been reported.

## Acquired Porphyria

(Porphyria Cutanea Tarda; Porphyria Cutanea Tarda Symptomatica; Symptomatic Porphyria; Idiosyncratic, Idiopathic, or Constitutional Porphyria)

Acquired porphyria is characterized clinically by photosensitive skin lesions and biochemically by the excessive hepatic synthesis and urinary excretion of porphyrins, especially uroporphyrin I. This form of porphyria always occurs in association with liver disease, usually of alcoholic or toxic origin.

## Etiologic Factors and Prevalence

Acquired porphyria probably is the most commonly recognized disorder of porphyrin metabolism.<sup>136</sup> It is particularly common among the Bantu population of South Africa,<sup>86</sup> where it appears to be associated with hepatic iron overload and the excessive consumption of a variety of home-brewed alcoholic beverages.<sup>86,133</sup> It also occurs in other countries in patients with alcoholic liver disease<sup>17,41,133</sup>; however, it is an uncommon complication of this disorder. In one study of 360 patients with alcoholic cirrhosis, porphyria was detected in only seven.<sup>171</sup> Possibly reflecting a difference in alcohol consumption, acquired porphyria is considerably more common in males than in females. The disease tends to begin in middle life, especially in persons between 40 and 50 years of age.

The observation that only a small proportion of alcoholic patients acquire porphyria has led a number of investigators to suggest that an inherited, constitutional idiosyncrasy may be an etiologic factor.<sup>22,171,173</sup> As yet, there is little direct evidence of such an abnormality. Most family studies have not demonstrated evidence for such an idiosyncrasy. However, acquired porphyria has been described in one set of identical twins, both alcoholics,<sup>171</sup> and a sibling of another patient had slightly increased values for urinary uroporphyrin and fecal coproporphyrin.<sup>22</sup> In the African patients, no evidence of a familial incidence has been found, even when alcohol

consumption among family members was similar.<sup>86,153</sup>

In Turkey, between 1956 and 1961, an epidemic of acquired porphyria involving more than 3000 persons occurred as the result of exposure to a seed wheat fungicide, hexachlorobenzene.<sup>134,135,159,163</sup> Members of both sexes were affected, and many of the subjects were children. The syndrome was later reproduced in rats by administering hexachlorobenzene.<sup>157,162</sup>

Estrogens have been implicated in 29 patients with acquired porphyria.<sup>160,165</sup> Of these, 23 were men, 20 of whom had been treated with estrogen preparations, usually diethylstilbestrol, for carcinoma of the prostate.<sup>160</sup> However, porphyria has also been described in women receiving estrogens, including natural estrogens, for symptoms of the menopause.<sup>163</sup>

Acquired porphyria also has been associated with exposure to several other chemical agents and with certain illnesses (Table 32-4). These occurrences are relatively uncommon, having been reported only in one or a few patients.

### Clinical Description

The manifestations of the disturbance in porphyrin metabolism are limited to the skin and urine. The observed photosensitive skin lesions are indistinguishable from those associated with variegate porphyria (page 1031). Almost all the patients notice that their urine has a distinct red color.<sup>153</sup> These manifestations are accompanied by signs and symptoms of the underlying liver disease. There is no good correlation, however, between the occurrence of porphyria and the degree of liver disease.

### Laboratory Findings

These patients excrete greatly increased amounts of porphyrins, especially uroporphyrin, in the urine. In a study of 66 patients, the urine uroporphyrin averaged 2819  $\mu\text{g}/\text{l}$ , and exceeded 1000  $\mu\text{g}/\text{l}$  in 70% of the group (normal <40  $\mu\text{g}/24$  hr).<sup>139</sup> Urine copro-

porphyrin averaged 560  $\mu\text{g}/\text{l}$  (normal <200  $\mu\text{g}/24$  hr). With more precise chemical techniques, uroporphyrin I was found to be the predominant porphyrin excreted.<sup>138,156</sup> However, increased amounts of uroporphyrin III, coproporphyrins I and III, and porphyrins with 7, 6, and 5 carboxyl groups also were found. In urine from rats with hexachlorobenzene-induced porphyria, type III isomers predominated.<sup>162</sup>

Normal or only slightly increased amounts of porphyrins are excreted in the feces.<sup>140</sup> However, unusual tetracarboxylic porphyrins, distinct from coproporphyrin, have been isolated from the feces of patients with acquired porphyria and from rats given hexachlorobenzene.<sup>141</sup>

The serum iron concentration often is increased. It exceeded 300  $\mu\text{g}/\text{dl}$  in 25% of Africans with the disease.<sup>153</sup> In the United States, in four patients from a series of 20, transferrin saturation was greater than 70%.<sup>143</sup>

Laboratory findings indicating liver disease vary considerably from one patient to another. There may be mild degrees of jaundice and slight to moderate elevations in serum transaminase levels. Liver biopsy usually demonstrates portal fibrosis, hepatic cell

necrosis, and varying degrees of iron overload.<sup>153,169</sup>

### Pathogenesis

Iron overload has been implicated in the pathogenesis of porphyria associated with alcoholic liver disease on the basis of several observations (1) excessive hepatic iron is almost invariably found<sup>142,169</sup>; (2) removal of iron by phlebotomy<sup>113,172</sup> or the administration of chelating agents<sup>167</sup> induces clinical and biochemical remission; and (3) administration of iron is followed by relapse.<sup>146</sup> Furthermore, in an *in vitro* system derived from hepatic tissue, ferrous iron was shown to inhibit the enzymes, uroporphyrinogen cosynthetase and decarboxylase (Fig. 32-1, reactions 4 and 5), and to increase the total synthesis of porphyrin from PBG.<sup>150</sup>

It seems reasonable that this effect of iron accounts for some of the observed abnormalities in patients with acquired porphyria. However, since iron overload by itself does not induce porphyria, the cellular and subcellular location of the iron as well as its chemical form may be critical to the development of the disease.

The activity of ALA synthetase has been studied by several investigators with conflicting results.<sup>68,92,137,165</sup>

### Treatment

Exposure to a toxic agent, if identified, should be eliminated. Abstinence from alcohol can lead to remissions in patients with porphyria associated with alcoholic liver disease<sup>171</sup>; however, removal of iron by phlebotomy can induce remissions even if alcohol intake continues. In general, 500 ml of blood can be removed every two weeks. In one series of 20 patients, remission was achieved in 18 by the removal of 2.5 to 8.5 l of blood over a period of three to eight and one-half months.<sup>143</sup> Of these, 14 remained in remission over periods of one to three and one-quarter years; of two in whom relapse occurred, one was successfully retreated.

Chloroquine has been employed in the treatment of patients with acquired porphyria,

but its use entails significant risks. Following the administration of 0.5 to 1.0 g/day for several days, a large portion of the uroporphyrin stored in the liver is excreted in the urine.<sup>145,168,170</sup> This "purging" effect apparently results from the formation of an easily excreted, water-soluble complex between uroporphyrin and the drug.<sup>164</sup> Following the chloroquine purge, a clinical and biochemical remission lasting up to one year may occur. Unfortunately, the chloroquine effect is accompanied by malaise, anorexia, fever, and signs of hepatocellular damage,<sup>145,168</sup> possibly because of injury to hepatic mitochondria.<sup>164</sup> These reactions are usually transient and the patients recover within a few days. Hemolytic anemia and ascites also have been reported.<sup>170</sup> Because of the potential danger of the hepatic reaction and also because phlebotomy appears to be relatively safe and effective, chloroquine must be considered to be an experimental and somewhat dangerous form of therapy. It should be used only under highly selected and carefully controlled circumstances. It is possible that the use of lower doses may make the drug safer without impairing its efficacy.<sup>161</sup>

Still another form of therapy is alkalization of the urine by administration of sodium bicarbonate, usually in a dose of 1.3 g three times daily.<sup>158</sup> With this treatment, eight of 10 patients improved clinically and biochemically. However, it was considered possible that the observed responses were related to changes in alcohol consumption, and the need for a controlled study was acknowledged.

In another uncontrolled study, eight patients with hexachlorobenzene-induced porphyria improved when treated with the chelating agent, disodium ethylenediamine tetraacetic acid (EDTA).<sup>159</sup>

# Part IV

## Disorders of Platelets and Hemostasis

Except for that which occurs during menstruation, spontaneous bleeding is abnormal. Surprisingly little blood is lost from even large injuries. This is a consequence of the efficiency with which vascular integrity is normally maintained and the rapidity with which it is restored following injury. In general, these phenomena reflect the functional effectiveness of the hemostatic apparatus (Chapters 9 and 10). It must be recognized, however, that the adequacy of hemostasis is only relative, and, despite the presence of normal vessels, platelets, and coagulation factors, bleeding can occur as the result of localized pathologic processes.

The following seven chapters will deal with disorders which result from abnormalities of the hemostatic process. Chapter 33 will summarize the diagnostic approach to these disorders, and includes a brief discussion of laboratory methods for their study. In the chapters which follow, individual disorders will be considered in five categories: quantitative variations of platelets in disease (Chapter 34), qualitative disorders of platelet function (Chapter 35), bleeding disorders due to vascular abnormalities (Chapter 36), hereditary coagulation disorders (Chapter 37), and the acquired coagulation disorders (Chapter 38). The pathophysiology of thrombosis and the principles of antithrombotic therapy, insofar as they pertain to the hemostatic apparatus, are summarized in Chapter 39.

## SECTION 1: *Approach to Problems of Hemostasis and Coagulation*

# *The Diagnostic Approach to the Bleeding Disorders*

Clinical Evaluation of the Bleeding Patient  
Manifestations of Disordered Hemostasis  
Clinical Features of the Hereditary Bleeding Disorders  
Clinical Features of the Acquired Bleeding Disorders  
Laboratory Methods for the Study of Hemostasis and Blood Coagulation  
Tests of the Vascular and Platelet Phases  
Tests of the Coagulation Phase  
Initial Laboratory Approach  
The Utility of Screening Tests  
Confirmatory Tests  
Laboratory Evaluation in the Newborn

### **Clinical Evaluation of the Bleeding Patient**

The importance of clinical evaluation in patients with bleeding disorders should neither be overemphasized nor minimized. The presence of a generalized disorder of hemostasis is often immediately and dramatically obvious, and in many cases there is nothing about the clinical picture to suggest any particular type of bleeding disorder. Nevertheless, a careful evaluation of the presenting complaint can often provide valuable clues as to whether the abnormality resides in the vessels, platelets, or the process of blood coagulation; a carefully obtained history can usually establish whether the disorder is hereditary or acquired; the physical examina-

tion may reveal findings such as the characteristic skin lesions of hereditary hemorrhagic telangiectasia, which alone may provide the diagnosis in a previously perplexing bleeding problem. The laboratory should supplement and not supersede a careful review of the history and the physical examination, if it is to be used to maximum advantage in terms of time and expense.

### **Manifestations of Disordered Hemostasis**

Certain signs and symptoms are virtually diagnostic of disordered hemostasis. They can be arbitrarily divided into two groups: those which are more frequently seen in disorders of blood coagulation, and those which are commonest in disorders of the vessels and platelets. The latter group is frequently referred to by the descriptive term "purpuric disorders," owing to the prominence of cutaneous and mucosal bleeding. The clinical findings that are most valuable in distinguishing between these two broad categories are summarized in Table 33-1. Although these criteria are relative, they provide valuable clues to the probable diagnosis<sup>5,8,14</sup> if applied to the predominating clinical features in a given patient.

### **Bleeding into Skin and Soft Tissues**

✎ **Petechiae** are characteristic of an abnormality in the vessels or the platelets, eg, throm-

**Table 33-1. The Clinical Distinction between Disorders of Vessels and Platelets and Disorders of Blood Coagulation**

<i>Findings</i>	<i>Disorders of Coagulation</i>	<i>Disorders of Platelets or Vessels ('Purpura' disorders)</i>
Petechiae	Rare	Characteristic
Deep dissecting hematomas	Characteristic	Rare
Superficial ecchymoses	Common, usually large and solitary	Characteristic, usually small and multiple
Hemarthrosis	Characteristic	Rare
Delayed bleeding	Common	Rare
Bleeding from superficial cuts and scratches	Minimal	Persistent, often profuse
Sex of patient	80-90% of hereditary forms occur only in males	Relatively more common in females
Positive family history	Common	Rare

bocytopenia, and are exceedingly rare in the coagulation disorders. These lesions (Fig. 33-1) are small capillary hemorrhages which range from the size of a pinhead to much larger and characteristically develop and regress in crops. They are most conspicuous in areas of increased venous pressure, eg, the dependent portions of the body and areas subjected to pressure or constriction from girdles or stockings. In scurvy, petechiae may be distributed around hair follicles in the "saddle area" of the thighs and buttocks (Fig. 36-10, page 1150). Petechiae must be distinguished from small telangiectases and angiomatous (Table 36-3, page 1147).

In the purpuric disorders, petechiae commonly are associated with multiple superficial ecchymoses, which usually develop without perceptible trauma but seldom spread into deeper tissues. Small isolated ecchymoses are common in apparently normal women, especially on the legs, and in small children.

Although large superficial ecchymoses may be seen in the coagulation disorders, the most characteristic lesion is the large spreading hematoma (Fig. 33-2). Such hematomas may arise spontaneously or follow very trivial trauma and frequently spread to involve an entire limb by dissecting muscles and deep fascial spaces, often with little discoloration of the overlying skin.

### Hemarthrosis

Hemorrhage into synovial joints is virtually diagnostic of a severe hereditary coagulation disorder, most commonly hemophilia A or hemophilia B, and is rare in disorders of the vessels and platelets or in acquired coagulation disorders. This disabling symptom (Fig. 33-3) often develops without discoloration or other external evidence of bleeding, and the patient may attribute the symptoms to arthritis rather than to bleeding. Subperiosteal hemorrhages in children with scurvy, and swollen painful joints which may develop in some patients with allergic purpura, occasionally may be confused with hemarthrosis (Chapter 36).

### Traumatic Bleeding

The unavoidable trauma of daily life and even minor surgical procedures are a greater challenge to hemostasis than any test yet contrived in the laboratory. In contrast to "spontaneous" bleeding manifestations, bleeding following trauma in a person with a hemorrhagic diathesis differs in a quantitative way from that which would normally be expected, ie, in terms of amount, duration, and magnitude of the inciting trauma. It is extremely difficult to assess such variables

accurately, however. The amount of blood lost usually is exaggerated by the patient. Whether or not transfusions were required and the number administered may serve as a rough guide. The patient's statement concerning the duration of bleeding is more reliable. Detailed inquiry as to past injuries and

operations must be made, since the patient is likely to forget procedures or injuries which were uncomplicated and dwell on those in which bleeding was a problem.

In the coagulation disorders, the onset of bleeding following trauma frequently is delayed. For example, bleeding following a

Fig 33-1. Strongly positive reaction to the tourniquet test in a patient with chronic idiopathic thrombocytopenic purpura. The platelet count was  $40 \times 10^9/l$ , the bleeding time 42 minutes. Note that there are few petechiae in the area compressed by the blood pressure cuff.

Fig 33-2 Large dissecting hematoma of thigh in a patient with hemophilia A. The lesion resulted from a slight bump to the inguinal area, and spread to involve the entire thigh (Courtesy of Dr John Lukens)

tooth extraction may stop completely only to recur in a matter of hours and persist despite the use of styptics, vasoconstrictors, and packing. The temporary hemostatic adequacy of the platelet thrombus despite defective blood coagulation may explain this phenomenon of delayed bleeding, as well as the fact that patients with coagulation disorders seldom bleed abnormally from small superficial cuts, eg, razor nicks. In contrast, post-traumatic or post-surgical bleeding in thrombocytopenia usually is immediate in onset, as a rule responds to local measures and rarely is as rapid or voluminous as that encountered in the coagulation disorders, but it may persist for hours or days from surprisingly small injuries.

Valuable information often is obtained by a careful review of dental procedures, since most patients will have had one or more teeth extracted at some time during their life. Inquiry should clarify whether the extractions were single or multiple, the size and location of the tooth or teeth, any therapy given, and

the amount, if any, of direct operative trauma.<sup>121</sup> The amount of bleeding normally encountered varies greatly, but as a rough guide it may be stated that the uncomplicated extraction of a single molar tooth may result in brisk bleeding for up to one hour and slight oozing for up to two days in normal persons.<sup>118</sup> Bleeding normally is more profuse from upper than from lower sockets and is more marked following extraction of molar teeth, particularly impacted third molars ("wisdom teeth"), than after removal of other teeth. In the hereditary coagulation disorders, the shedding of deciduous teeth is frequently uncomplicated.

The response to trauma is an excellent "screening test" for the presence of a hereditary hemorrhagic disorder, and a history of surgical procedures or significant injury without abnormal bleeding is equally good evidence against the presence of such a disorder. The removal of molar teeth is a "major" challenge to hemostasis, as is a tonsillectomy, and it is a rare hemophiliac, however mildly affected, who can withstand these procedures without undue bleeding.

### Miscellaneous Bleeding Manifestations

Spontaneous bleeding from bodily orifices may complicate any significant hemorrhagic diathesis, eg, menorrhagia, metrorrhagia, hematuria, hematemesis, melena, epistaxis, gingival bleeding. These symptoms occur with approximately equal frequency in purpuric disorders and coagulation disorders, and when they are the first or predominant manifestations they may erroneously be attributed to a more familiar local lesion. Severe menorrhagia may be the sole complaint of women with von Willebrand's disease, mild thrombocytopenia, or autosomally inherited coagulation disorders. Recurrent gastrointestinal bleeding or epistaxis in the absence of other bleeding manifestations is common in hereditary hemorrhagic telangiectasia. A coagulation disorder or a disorder of platelet function should be looked for if protracted hematuria is the only symptom.

Bleeding into serous cavities and internal

fascial spaces may create serious diagnostic problems, and is not uncommon in the hereditary coagulation disorders. In hemophilia, retroperitoneal hemorrhage or bleeding into the psoas sheath may mimic appendicitis, and hemorrhage into the bowel wall may be confused with intestinal obstruction. Signs and symptoms which simulate a variety of acute intra-abdominal disorders may also be seen in allergic purpura (Chapter 36). Bleeding into the central nervous system may complicate thrombocytopenia, and may follow minor trauma in the coagulation disorders. Multiple small retinal hemorrhages are common in thrombocytopenia and other purpuric disorders, but are uncommon in the hereditary coagulation disorders. Large hematomas of the orbit may be seen in the latter. The coexistence of bleeding and thromboembolic phenomena, or bleeding from previously intact venipuncture sites, suggests the presence of diffuse intravascular coagulation (DIC).<sup>44,102</sup> Protracted wound healing and

abnormal scar formation have been described in hereditary afibrinogenemia, the dysfibrinogenemias, and in factor XIII deficiency<sup>48</sup> (Chapter 37). Hemoptysis is rarely due to a hemorrhagic disorder.

### Clinical Features of the Hereditary Bleeding Disorders

A hereditary bleeding disorder is suggested by the onset of bleeding symptoms in infancy and childhood, a positive family history, particularly if it reveals a consistent genetic pattern, and laboratory evidence of a single or "isolated" abnormality, most commonly the deficiency of a single coagulation factor.

#### Age at Onset: Bleeding in the Neonate

Birth and the neonatal period provide unique challenges to the hemostatic mecha-

Fig 33-3. Acute hemarthrosis and its sequelae in a patient with hemophilia B. Note the periarthral swelling in the left leg and the marked atrophy of the thigh muscles as a result of recurrent hemarthrosis (Courtesy of Dr. John Lukens).

nism,<sup>68,101</sup> and bleeding during the first month of life often provides the first evidence of a hereditary disorder of hemostasis. Small cephalohematomas and petechiae are common in the newborn as a result of the trauma of delivery.<sup>68</sup> Large cephalohematomas which progressively increase in size may result from hemophilia, but are more common in acquired bleeding disorders such as hemorrhagic disease of the newborn (Chapter 38). Bleeding from the umbilical stump and following circumcision is characteristic of the latter syndrome, but is uncommon in the hereditary coagulation disorders,<sup>68</sup> with the exception of hypofibrinogenemia<sup>17</sup> and factor XIII deficiency.<sup>48</sup> In these disorders, the onset of cord bleeding may be delayed. In the evaluation of bleeding in the neonate, it should be remembered that hematochezia and hematemesis may originate from swallowed blood of maternal origin.

When a hereditary coagulation disorder is not associated with bleeding in the neonatal period, or when the significance of bleeding is overlooked, the disorder may become clinically "silent" for a time. Hematomas may be first seen only when the child becomes active. Hemarthrosis commonly does not develop until three to four years of age.

Rarely, the date of onset of bleeding may be difficult to establish, and it may be difficult to distinguish between a mild hereditary hemorrhagic disorder and the insidious onset of an acquired defect. Patients with mild hereditary coagulation disorders may enter adult life before characteristic bleeding manifestations occur. In these cases, and in some forms of hereditary thrombocytopenia and disordered platelet function, it is not uncommon to obtain a history of marked post-traumatic bruising and hematoma formation which have come to be accepted by the patient as "normal." In hereditary hemorrhagic telangiectasia, the lesions become more prominent with advancing age, and may not be symptomatic until middle age. Similarly, in the patient with the Ehlers-Danlos syndrome, bleeding may not be a problem until adult life.

## The Family History

This is of great importance in the evaluation of bleeding disorders. Details of the various genetic patterns which may be encountered are discussed elsewhere. In autosomal dominant traits with characteristic symptoms and high penetrance, such as hereditary hemorrhagic telangiectasia, an accurate pedigree spanning several generations can often be obtained (Fig. 36-5, page 1145). The presence of characteristic bleeding manifestations in male siblings and maternal uncles is virtually diagnostic of X-linked recessive inheritance which characterizes hemophilia A and hemophilia B. In such X-linked traits, the family history also may be helpful in a negative sense, ie, it may clearly exclude the disorder in certain offspring such as the sons of a known hemophiliac.

The limitations of the family history, however, are much greater than is commonly realized. "Hearsay" history is very difficult to evaluate, and it is difficult and often impossible to assess the significance of "easy bruising," or to differentiate between manifestations of a generalized bleeding disorder and more common localized lesions, eg, peptic ulcers, uterine leiomyomas. In affected families, a bewildering variety of unrelated symptoms are frequently attributed to bleeding.

It must be emphasized that a negative family history is of no value in excluding a hereditary coagulation disorder in an individual patient; eg, as many as 40% of patients with hemophilia A will have a negative family history.<sup>13</sup> The family history is usually negative in the autosomal recessive traits, and consanguinity, which is commonly present in these kindreds, is notoriously difficult to document or exclude.

## Clinical Features of Acquired Bleeding Disorders

Generalized bleeding may be a prominent feature of a wide variety of disorders which encompass virtually the entire field of med-

icine. Bleeding manifestations usually are less severe than in the hereditary forms, and the clinical picture often is dominated by evidence of the underlying disorder rather than by bleeding alone. In contrast to the hereditary forms, a multiple hemostatic defect is commonly present, often including thrombocytopenia as well as significant coagulation abnormalities.

In general, the study of the acquired bleeding disorders should emphasize the patient and not the laboratory. A carefully taken history and the physical examination will often reveal the cause of thrombocytopenia, eg, a drug, acute leukemia. In most vascular disorders, eg, senile purpura, allergic purpura, scurvy, and amyloidosis, the history and physical examination are of primary diagnostic importance whereas the laboratory has little to offer.

### Drug History

The importance of an exhaustive interrogation regarding drug use and chemical exposure cannot be overemphasized. The list of drugs which are associated with thrombocytopenia (Table 34-5, page 1084) or vascular purpura (Table 36-1, page 1137) grows longer each year. Less common but more serious is drug-induced aplastic anemia, which may first present with bleeding (Fig. 56-4, page 1755). A large number of commonly used drugs (Table 35-1, page 1120), notably aspirin, impair platelet function. These drugs are a heretofore unrecognized cause of mild purpura and also produce confusing laboratory abnormalities which may lead to expensive and unnecessary laboratory studies. The same drugs may provoke bleeding when administered to patients with hereditary coagulation disorders, eg, hemophilia A.

Coagulation abnormalities may also result from drug ingestion. Drugs which potentiate or antagonize the anticoagulant effects of coumarin anticoagulants may lead to bleeding or erratic laboratory control. The surreptitious ingestion of such anticoagulants is not uncommon (Chapter 39).

## Laboratory Methods for the Study of Hemostasis and Blood Coagulation

There is no single test which is suitable for the laboratory evaluation of the overall process of hemostasis and blood coagulation, but methods of varying complexity and utility are now available for assessing various components and functions individually. The following discussion will emphasize those methods which are simple and widely available in routine laboratories. The interpretation of the most commonly used tests and the range of values obtained in normal subjects with representative techniques are summarized in Table 33-2. Definitive methods usually require a specially equipped laboratory and trained personnel, and will be discussed here from a general standpoint only. Additional comments concerning the utility and limitations of the various methods will be found in later chapters dealing with individual disorders. For details concerning such definitive methods, the reader is referred to more comprehensive works devoted entirely to this subject.<sup>10,24,51,62,102,138</sup>

### Tests of the Vascular and Platelet Phases

#### The Bleeding Time

Hemostasis in a small superficial wound, such as that produced in measuring the bleeding time, depends on the rate at which a stable platelet thrombus is formed, and thus measures the efficiency of the vascular and platelet phases. It does not, however, discriminate between vascular defects, thrombocytopenia, and platelet dysfunction. The bleeding time leaves much to be desired in terms of reproducibility, since no two skin areas are exactly the same and it is impossible to produce a truly standard wound.<sup>135</sup>

Despite these intrinsic limitations, the bleeding time is valuable when carefully performed. When determined by the modified Ivy technique,<sup>37</sup> it is usually prolonged when the platelet count is below  $100 \times 10^9/l$ ,<sup>45</sup> as

Table 33-2. Interpretation of Common Tests of Hemostasis and Blood Coagulation

Test	Normal Range ( $\pm 2$ SD) and Method	Common Causes of Abnormalities*
1 Platelet count	140-440 $\times 10^9/l^{17,18}$	Thrombocytopenia Thrombocytosis
2 Bleeding time		
Ivy	1-9 mins <sup>19</sup> †	Thrombocytopenia, von Willebrand's disease, platelet dysfunction, vascular disorders (uncommon), severe coagulation disorders (rare)
Duke	1-4 mins <sup>15</sup>	
3 Partial thromboplastin time		
Standard	68-82 secs <sup>9¶</sup>	Deficiencies or inhibitors of factors XII, XI, IX, VIII, X, V, prothrom- bin, or fibrinogen
Activated	32-46 secs <sup>10¶</sup>	
4 Plasma prothrombin time	11-15 secs <sup>11‡</sup>	Deficiencies or inhibitors of factors VII, X, V, prothrombin or fibrinogen
5 Coagulation time		
Glass tubes	8-18 mins <sup>12§</sup>	As $\pm 3$ above, but abnormal only in severe deficiencies
6 Thromboplastin generation test <sup>7,10</sup>	§	Deficiencies of inhibitors of factors XII, XI, IX, VIII, V or X
Plasma abnormal	§	Deficiency of factors V or VIII
Serum abnormal†	§	Deficiency of factors X or IX
Plasma and serum abnormal†	§	Deficiency of factors XII, XI, or inhibitor
7 Plasma thrombin time	13-17 secs <sup>4‡</sup>	Afibrinogenemia, dysfibrinogenemia and hypofibrinogenemia, inhibi- tors of thrombin or fibrin poly- merization
8 Fibrinogen assay	160-415 mg/dl <sup>5‡,11§</sup>	Afibrinogenemia, dysfibrinogenemia and hypofibrinogenemia, inhibi- tors of thrombin or fibrin polymer- ization

\*Tests 3 through 8 are affected by heparin

†Deficiencies of factor XI or factor XII may produce either a combined serum and plasma abnormality or a serum abnormality alone

§Normal range varies widely and must be interpreted in terms of control system

¶Minor variations depending on exact technique employed

‡Significant variations depending on thromboplastin used

well as in the majority of patients with von Willebrand's disease or disorders of platelet function. Contrary to theory, this test is only inconsistently abnormal in most disorders attributed to abnormalities of the vessels. The bleeding time is commonly prolonged in hereditary afibrinogenemia, probably as the result of platelet dysfunction (page 1127), and is occasionally prolonged in other severe coagulation disorders (Chapter 37).

### Related Methods

The template bleeding time,<sup>67,92</sup> the "secondary" bleeding time,<sup>19</sup> and various automated methods<sup>131</sup> are modifications of the Ivy method which may be more sensitive and reproducible than the original procedure. The carlobe bleeding time performed by the Duke method<sup>113</sup> is less sensitive than the modified Ivy method, particularly in the detection of

patients with von Willebrand's disease.<sup>97</sup> The aspirin tolerance test assesses the effect of a standard dose of aspirin on the Duke bleeding time.<sup>113</sup> This has been proposed as a method of detecting mild von Willebrand's disease, but the diagnostic value of the method is doubtful.<sup>92,143</sup> The administration of aspirin will prolong the bleeding time slightly in normal subjects and in patients with hemophilia A and hemophilia B,<sup>92</sup> as well as in patients with von Willebrand's disease, and may be dangerous in patients with coagulation disorders.

In the tourniquet test,<sup>127a</sup> a "standard" increase in venous and capillary pressure is produced for a short time by means of a sphygmomanometer.<sup>37</sup> In the presence of vascular abnormalities, or insufficient or abnormal platelets, petechiae may develop. The number and size of these lesions are an extremely crude index of the efficiency of the vascular and platelet phases. The tourniquet test correlates poorly with the platelet count; many normal subjects will develop some petechiae and many patients with bleeding due to vascular or platelet disorders will not. As a consequence, the tourniquet test is of little value as a screening test for disordered hemostasis.

Despite a promising beginning,<sup>82</sup> capillary microscopy has proved of little value in the study of bleeding disorders.

### Platelet Enumeration

Platelets are considerably more difficult to count than erythrocytes or leukocytes. This is to be expected in dealing with structures of such small size whose major physiologic attributes are adhesion to foreign surfaces and rapid aggregation following even minimal trauma.

In general, techniques for platelet counting may be divided into four groups, namely (1) *hemocytometer or direct methods*, in which whole blood is diluted and the platelets are counted in much the same way as leukocytes or erythrocytes; (2) *indirect methods*, in which red cells or white cells are enumerated directly and their proportion to platelets is

determined in a stained blood smear; (3) *semi-automated methods*, in which the number of platelets present in plasma prepared by sedimentation or centrifugation is determined in an electronic particle counter; and (4) *fully automated electronic methods*. Many other methods for platelet counting and innumerable technical modifications have been described, each with certain advantages and disadvantages.<sup>16,109</sup> An estimate of platelet numbers in a well-prepared blood smear by an experienced observer serves as a valuable check on the platelet count as determined by any method.

### Direct Methods

In the method of Brecher and Cronkite,<sup>27</sup> the difficulty in distinguishing platelets from other particles is minimized by the use of phase contrast microscopy and dilution of the blood in 1% ammonium oxalate, a reagent which hemolyzes the red cells and provides a clear background. A long working distance phase condenser, a 43 X medium dark contrast phase objective, flat-bottomed hemocytometers, and thin coverslips (No. 1 or 1½), rather than the usual hemocytometer coverglass, are required. Platelet counts can be carried out on either venous or capillary blood, but the latter is subject to the greater errors.<sup>27</sup> The earlobe should not be used as a source of capillary blood because the fine hair there is said to favor adhesion of the platelets. Venous blood may be collected without anticoagulant in a siliconized test tube<sup>27</sup> or on a siliconized slide, but the preferred method is the use of di- or tripotassium or disodium EDTA (2.5 to 5 mg/2 ml of whole blood). Double oxalate and citrate are not recommended as anticoagulants for platelet counting. The use of cocaine as a diluent may further improve the visualization of platelets.<sup>109</sup> The principles of phase contrast microscopy are described elsewhere<sup>37</sup> (Chapter 1).

Despite the special equipment required, the Brecher-Cronkite technique probably represents the best available compromise between cost, time, and accuracy, even though the

error of replication is still relatively high (1 CV = 7-17%).<sup>37,55,60,88</sup> In general, errors tend to result in low platelet counts. This may be because of a poorly collected blood sample, in which platelet aggregation has been induced by mechanical trauma or contaminating tissue "juice" or thrombin, or from adherence of platelets to particles of debris on the glassware used or in the diluting fluid. Erroneously high counts may result from fragmentation of platelets without complete dissolution, or the counting of particles of debris, eg, crystals of some salts making up the diluting fluid, dye, bacteria, portions of hemolyzed red cells, broken leukocytes. These errors can be minimized by the use of scrupulously clean glassware. Diluting fluids should always be refiltered before each determination.

The Rees-Ecker method is the progenitor of the above technique, which it resembles in most respects. Because the diluting fluid<sup>37</sup> is less satisfactory and an ordinary light microscope is used, there is much greater difficulty in visualizing the platelets. When counting platelets by this technique, the observer should control the fine adjustment of the microscope in order to obtain the critical focusing that reveals the characteristic highly refractile, silvery appearance of the platelets. The platelets are lilac-colored,  $\frac{1}{4}$  to  $\frac{1}{2}$  the diameter of the red corpuscles, and usually oval or rod- or comma-shaped. They may be seen singly or in groups. It is important to distinguish platelets from globules of oil, irregularly shaped debris floating on the upper layers of fluid, strings of cocci, and other particles which may be found in the fluid.

### Semi-automated Methods

In the method of Bull et al.,<sup>34</sup> whole blood is collected in EDTA and either allowed to settle spontaneously or is centrifuged briefly. The platelets in the supernatant platelet-rich plasma are then enumerated by means of an electronic particle counter.<sup>29,33,88</sup> The instrument must be equipped with a modified 50 to 70  $\mu$ m aperture tube, and should be

calibrated with an external standard such as latex particles, bacteria,<sup>83</sup> or formalinized platelets. Extreme caution and frequent blank runs are required to keep diluting solutions free of contaminating particles. Platelet cold agglutinins<sup>41</sup> and abnormal amounts of plasma proteins in the various paraproteinemias<sup>24</sup> may produce falsely low platelet counts, whereas carryover from sample to sample may result in overestimation of platelet numbers, particularly in thrombocytopenic samples.<sup>29</sup> Owing to the high dilution of the platelet-rich plasma required for electronic counting (1:3000 to 1:5000), the use of a highly accurate diluting device is recommended.<sup>26</sup> A slide rule which simplifies corrections for hematocrit and coincidence factors is now available commercially (Coulter).<sup>33</sup>

Semi-automated methods improve the precision of the platelet count substantially (CV of replicate samples = 1.2 to 4%<sup>33,55,60,83</sup>). However, they require more expensive equipment and represent little saving of time as compared with manual methods unless 30 or more counts must be made in one day.<sup>26</sup> Centrifuges must be calibrated carefully and frequently, since the centrifugal force employed in preparing the platelet-rich plasma is critical.<sup>26</sup> Significant errors may result from unpredictable variations in the percentage of platelets recovered in the supernatant plasma prepared by either sedimentation or centrifugation.<sup>50</sup>

### Fully Automated Methods

Instruments for totally automated platelet counting are now available commercially. For example, with the Hemalog (Technicon), whole blood samples are collected in EDTA, diluted, and hemolyzed in 2 M urea, and platelets are enumerated by means of an optical particle counter which employs the principle of reverse darkfield microscopy.<sup>31</sup> The precision of platelet counting with this instrument is equal to or even greater than that obtained with semi-automated methods.<sup>64,117</sup> Carryover of platelets from samples with high counts to subsequent samples has been

a problem, but can be eliminated by repeating the determination.

Although platelet counting is but one function of such "hematologic autoanalyzers," the disadvantages of these massive instruments are apparent, eg, size, great cost, considerable maintenance time. Their cost would seem justified only by a large volume of work, but their utility in this setting is undeniable. Evaluation of these instruments is still incomplete.

### Indirect Methods

These methods were originated prior to the advent of reliable direct methods, are quite inaccurate, and are not recommended. The simplest procedure is to note the number of platelets as compared with the number of red corpuscles or leukocytes in a stained blood smear. Fonio placed a drop of 14% aqueous solution of magnesium sulfate on the skin and punctured the finger through this in order to dilute the blood at once and to prevent aggregation of the platelets. Olef's method<sup>100</sup> is perhaps the best of the indirect procedures but is somewhat cumbersome. Dameshek's method<sup>40</sup> is similar but simpler.

Platelet counts made by indirect methods tend to be higher than those obtained by direct methods of enumeration. This is attributable in part to the tendency of red cells to concentrate at the edge of the smear, thus giving a falsely high ratio of platelets to red cells in the central areas where the count is likely to be made.<sup>26</sup>

### Normal Values for Platelets

Different normal values have been recorded, depending chiefly on the method used. Employing the Rees and Ecker method, the mean platelet count  $\pm 2$  SD in 80 healthy young adults was found to be  $241 \pm 100 \times 10^9/l$ ,<sup>125</sup> which would give a normal range of 140 to  $340 \times 10^9/l$ . Normal values for the Brecher-Cronkite method are  $250 \pm 90 \times 10^9/l$ , 95% of the counts ranging from 140 to  $440 \times 10^9/l$ .<sup>27</sup> Using his own method, Tocantins<sup>134</sup> found quite simi-

lar values. His figures were: cutaneous blood, 250; venous blood, 310; arterial blood, 350 with standard deviations of 58.5 to  $128 \times 10^9/l$ . Results obtained with the semi-automated method of Bull et al<sup>34</sup> were virtually identical to those obtained by Brecher and Cronkite. Similar normal values have been claimed for the totally automated instruments, but further documentation is needed.

Indirect counting methods have, in general, yielded much higher normal values. Thus, Olef,<sup>100</sup> using his own method, found an average count of  $514 \times 10^9/l$  (437 to 586). By Dameshek's method,<sup>40</sup> 500 to  $900 \times 10^9/l$  platelets were regarded as normal. As already stated, the highest counts recorded are not necessarily correct.

### Tests of Specific Platelet Functions

Owing to the rapid advances in knowledge concerning qualitative abnormalities of the platelets, the various techniques for measurement of specific platelet functions, formerly the province of the highly specialized research laboratory, are now being used with increasing frequency for diagnostic purposes.<sup>40a,149</sup>

### Platelet Adhesiveness

Numerous attempts have been made to measure the adhesion of platelets to foreign surfaces,<sup>69</sup> the greatest effort having been directed toward the development of a technique which detects the abnormality in primary hemostasis which is present in patients with von Willebrand's disease.<sup>18,118,143,149</sup> The diagnostic utility of these techniques in the various disorders of platelet function remains unclear.

The *in vivo* method of Borchgrevink<sup>18</sup> presumably measures the adhesion of platelets to the wound surface. Platelets are enumerated in the capillary blood issuing from a bleeding-time puncture, and adherent platelets are expressed as a percentage of the venous platelet count. As estimated by this

method, adhesion is influenced by all of the variables intrinsic to the bleeding time and by the hematocrit.<sup>69</sup> The results of the test are abnormal in many patients with von Willebrand's disease and in those with certain disorders of platelet function.

The retention of platelets within glass-bead columns (glass-bead "adhesion") has been studied by numerous methods, of which two appear to detect an abnormality in many patients with von Willebrand's disease. In the Salzman method,<sup>118</sup> venous blood is aspirated directly from the vein through a bead column and into a Vacutainer. Results are expressed as the percentage of the venous platelet count retained. The wide range of values obtained in normal subjects limits the usefulness of the technique. Modifications which provide a more standardized vacuum have been described.<sup>21</sup> Somewhat less cumbersome are *in vitro* methods in which heparinized whole blood<sup>21</sup> or "native" blood without anticoagulant<sup>70</sup> is passed through a bead column, and the percentage of retained platelets is determined. These methods are difficult to standardize,<sup>22,23</sup> and are exquisitely sensitive to *in vitro* platelet manipulation.<sup>131</sup> If measured in citrated plasma, retention appears to measure mainly the entrapment of platelet aggregates formed as the result of released ADP.<sup>63</sup>

The adhesion of platelets to collagen fibers *in vitro* is unaffected by strong chelating agents which completely inhibit ADP-induced aggregation. Thus, in platelet-rich plasma containing EDTA, adhesion to collagen may be assessed in the absence of aggregation. Techniques based on aggregometry<sup>127</sup> and the enumeration of free and adherent platelets<sup>145</sup> have been described. Abnormalities in collagen adhesion may be helpful in differentiating between various defects of the platelet release reaction (Chapter 35).

### Platelet Aggregation

Platelet aggregation may be estimated qualitatively both by microscopic and macroscopic techniques. The most commonly

used quantitative methods employ various aggregometers. In essence, these instruments are photometers modified so as to permit measurement of changes in optical density of a platelet suspension under conditions of constant temperature and continuous agitation (Fig. 33-4). Most instruments measure a combination of light scatter and absorption, and modifications which permit simultaneous nephelometric and photometric measurements have been developed.<sup>21,91a</sup> Platelet aggregation usually is studied in suspensions of citrated platelet-rich plasma. Techniques for the study of platelet aggregation in whole blood<sup>5a</sup> and of washed platelet suspensions also have been described.<sup>4</sup>

Adenosine diphosphate (ADP) in 5  $\mu$ M or higher concentrations produces platelet aggregation directly, and is independent of the release of platelet-contained ADP.<sup>66</sup> Various other aggregating agents act mainly by inducing the release of platelet-contained ADP, eg, a suspension of connective tissue particles ("collagen"),<sup>150</sup> epinephrine and

Fig. 33-4. The interpretation of aggregometer tracings. Tracing of platelet aggregation produced by a low concentration of ADP, illustrating normal changes in optical density (OD), ie, (1) a slight decrease due to dilution with aggregating agent, (2) a transient increase due to initial platelet swelling or shape change, (3) a rapid progressive decrease as platelet aggregates form, the size of which is roughly proportional to the amplitude of the oscillations in the tracing (4). The OD then reaches a nadir (5) from which maximal aggregation as a percentage of the initial OD may be calculated from the equation: maximal aggregation (%) =  $OD \text{ at } T_0 - \text{minimum } OD / OD \text{ at } T_0$ . Following this (6) a slow increase in OD due to disaggregation occurs under some conditions.

norepinephrine, and thrombin.<sup>149</sup> With epinephrine (5  $\mu$ M) a weak direct aggregating effect usually can be clearly delineated from the subsequent release reaction which produces a "secondary" wave of aggregation (Fig. 35-2, page 1125). Such "primary" and "secondary" waves of aggregation also may be seen with carefully titrated amounts of ADP (0.2 to 1.5  $\mu$ M).<sup>66</sup> Measurements of released ADP<sup>146</sup> and <sup>14</sup>C-labeled serotonin<sup>149</sup> provide more direct indices of the release reaction (page 394).

### Tests for Platelet Factor 3 Activity

Although the exact nature and significance of platelet factor 3 (PF-3) remain uncertain and controversial,<sup>83,84</sup> most data would suggest that the evolution of this procoagulant activity normally is intimately related to and dependent upon the process of platelet aggregation<sup>127</sup> (Chapter 9). Consequently, estimates of PF-3 activity provide mainly an indirect means of assessing these earlier steps. Despite the widespread use of the term "PF-3 release," it is probable that the activity which is measured by most techniques remains closely associated with the platelet membrane, having been activated or made "available" by various factors, eg, contact with foreign surfaces, ADP, thrombin (page 397). Techniques for the bioassay of PF-3 remain imperfect, despite the large number and variety of methods which have been tried.<sup>83,84</sup> Attempts to measure platelet factor 3 by chemical methods have thus far been unsuccessful.

Platelet suspensions may be prepared, washed, and tested for PF-3 activity in the thromboplastin generation test (TGT). Platelet concentration may be standardized by enumeration, nephelometry,<sup>23,24</sup> or by packed volume.<sup>51</sup> The major disadvantage of this technique is that when platelets are centrifuged into a "button" and washed, PF-3 is made "available" and may be removed and lost as a result. Another significant problem is that dilute platelet suspensions must be used in order to demonstrate an abnormality,<sup>51,84</sup> and the resulting long sub-

strate clotting times are quite variable even with normal platelets.<sup>84</sup> The coagulant activity of a platelet suspension following disruption of the cells by freezing and thawing or sonication is often assumed to be proportional to the total "content" of platelet factor 3. The diagnostic significance of this measurement is nevertheless unclear (page 397).<sup>84</sup>

Tests of kaolin-induced PF-3 availability<sup>63</sup> are more sensitive and reproducible than those based on the TGT. Both the activating surface and platelet concentration can be accurately standardized, and since the test is carried out in platelet-rich plasma, platelet manipulation prior to testing is minimized. In the simplest one-stage method,<sup>64</sup> kaolin and platelet-rich plasma are incubated, with mixing, for a time, and the mixture is then recalcified. The clotting time of such a mixture generally is proportional to the platelet factor 3 made "available" by kaolin. Nonspecific variations may be minimized by two-stage modifications.<sup>126,142</sup>

The one-stage serum prothrombin time, discussed below, and other estimates of prothrombin consumption still are widely used as screening procedures for PF-3 activity, mainly because they are simple to perform. If abnormal as the result of platelet dysfunction, prothrombin consumption will usually be corrected by the addition of small amounts of a platelet substitute.<sup>142</sup> The diagnostic significance of this phenomenon is uncertain.<sup>84</sup>

### Clot Retraction

Clot retraction is usually deficient when the platelet count is below  $50.0 \times 10^3/\mu\text{L}$ <sup>55</sup> and in a rare disorder of platelet function (thrombasthenia<sup>65</sup>, page 1119). It is normal in most other disorders of platelet function. Qualitative estimates of clot retraction can be made by incubating a tube of clotted blood, in which retraction is normally apparent within two hours. Simple quantitative methods for determining the extent of clot retraction have been described<sup>24</sup>; these are useful in the study of disordered platelet function and drug-induced autoimmune thrombocytopenias (page 1092).

### Tests of the Coagulation Phase

It is doubtful whether many of the innumerable minor technical variations which have found their way into methods for the study of blood coagulation have significantly improved the specificity or reproducibility of the commonly used tests. However, the "normal" range of almost every test will vary depending on the exact technique and reagents employed, and it is thus very important that the physician be aware of the normal range for the specific technique employed in a particular laboratory. In general, a meticulous method of performing the test is more important than the exact technique employed.

Blood samples obtained by means of traumatic venipunctures or from indwelling catheters<sup>76</sup> often are inadequate for coagulation studies. Even the small amounts of heparin used to flush indwelling catheters can produce marked coagulation abnormalities. A poorly collected blood sample is a far more common cause of inaccurate results than is technical error, and confusion and delay usually result when coagulation tests are performed on inadequate specimens.

#### *The Partial Thromboplastin Time*

The partial thromboplastin time (PTT) is a simple test of the intrinsic and common pathways of coagulation. When a mixture of plasma and a phospholipid platelet substitute is recalcified, fibrin forms at a normal rate only if the factors involved in the intrinsic pathway (factors XII, XI, IX, and VIII) and the common pathway (factors X, V, prothrombin, and fibrinogen) are present in normal amounts (Fig. 33-5). Platelet substitutes of various kinds may be used, eg, chloroform extract of brain<sup>5</sup> and other crude cephalin fractions, soybean phosphatides (Inosithin). In the PTT, such platelet substitutes are provided in excess, and the test is thus unaffected by platelets. However, platelet substitutes are only "partial" thromboplastins, and they are incapable of activating the extrinsic pathway, which requires "complete" tissue thrombo-

plastins. Thus, the PTT "bypasses" the extrinsic pathway and is unaffected by factor VII.

The PTT is somewhat more sensitive to deficiencies of factors VIII and IX than to factors XI and XII or factors involved in the common pathway,<sup>56</sup> but with most techniques the test will usually yield abnormal results if the plasma level of any of the essential factors is below 15 to 20% of normal. The PTT thus detects many mildly affected patients. The PTT also is prolonged by heparin and by inhibitors of any of the essential factors. As is the case with all one-stage tests, the PTT may be shortened by high levels of a single factor, most commonly factor VIII (page 421). Thus, a short PTT may signify any of the various "hypercoagulable" states (Chapter 39), and high levels of any factor involved may mask deficiencies of others.<sup>49</sup>

In the original method,<sup>79</sup> contact activation was provided by the glass tube, but the addition of "activators," such as ellagic acid, or particulate silicates such as Celite or kaolin, provides more optimal and standardized contact activation, and represents a significant improvement over the original nonactivated test.<sup>110</sup>

#### *The Plasma Prothrombin Time*

The production of fibrin via the extrinsic and common pathways (Fig. 33-5) requires tissue thromboplastin and factor VII, in addition to factors X and V, prothrombin, and fibrinogen. These pathways are measured by the plasma prothrombin time,<sup>111</sup> in which plasma is recalcified in the presence of excess tissue thromboplastin. This test does not require contact activation, and "bypasses" the intrinsic pathway and the factors concerned there, ie, factors XII, XI, IX, and VIII. Since tissue thromboplastins contain phospholipids which act as platelet substitutes, the test is unaffected by platelets. Of the five coagulation factors measured in the prothrombin time, ie, factors V, VII, and X, prothrombin and fibrinogen, three (prothrombin, factors VII and X) are vitamin K-dependent and are depressed by coumarin-like drugs. As

a result, the prothrombin time is the most widely used test for controlling anticoagulant therapy with such drugs (page 1244). The prothrombin time usually will be prolonged if the plasma levels of any of the requisite factors are below 10% of normal, and is relatively more sensitive to deficiencies of factors VII and X than to deficiencies of fibrinogen and prothrombin.<sup>9</sup> The prothrombin time also is prolonged by inhibitors of any of the essential factors, and by heparin, but it is much less sensitive to the anticoagulant action of heparin than is the PTT.

### Related Methods

Various modified techniques and thromboplastins have been developed to improve the utility of the prothrombin time in the control of coumarin anticoagulants<sup>104,105</sup> (Chapter 39). The expression of the prothrombin time as a "percentage" of normal may be misleading and is not recommended, since the dilution curves used to arrive at this figure often have little quantitative meaning. The prothrombin time performed with bovine brain thromboplastin or Thrombotest<sup>104</sup> is abnormal in patients with certain of the genetic variants of factor IX deficiency, but is normal in patients having the more common form of this disorder (page 1172). The venom of Russell's viper contains a unique thromboplastic substance which initiates coagulation by the direct activation of factor X, and does not require factor VII (page 425). The one-stage "prothrombin time" performed with this venom (the Stypven time)<sup>62</sup> thus serves to distinguish between deficiencies of factor VII and those of factor X (Fig. 33-4).

### The Coagulation Time

The coagulation time of whole blood is the most commonly misinterpreted coagulation test. In theory, fibrin formation in whole blood collected without contaminating-tissue thromboplastin proceeds via the intrinsic and common pathways, involves the same coagulation factors measured by the PTT, and requires factor 3 from the contained

platelets (Fig. 33-5). However, the coagulation time measures only the time required for the formation of the first traces of thrombin which suffice to produce a visible clot. Even the small amounts of platelet factor 3 which are available in severe thrombocytopenia are sufficient to produce these requisite traces of thrombin, and consequently the clotting time is unaffected by the number of platelets. For the same reason, the clotting time is significantly prolonged only in severe deficiencies of the various coagulation factors involved in the intrinsic and common pathways, and usually is normal when these factors are present in amounts which exceed 1% of normal plasma levels.<sup>123</sup> The test is unaffected by the level of factor VII. The coagulation time is thus informative only if it is significantly prolonged, and is a very poor screening test which seldom provides information not obtained from the PTT. It is prolonged by heparin, and is still widely used to control the use of this drug, but the PTT appears to be a more convenient and reproducible method (Chapter 39).

### Related Methods

The coagulation time of whole blood in plastic or silicone-coated tubes, and the recalcification time of platelet-poor plasma represent refinements of the glass tube whole blood coagulation time. Although somewhat more sensitive, these techniques do not alter any of the intrinsic limitations discussed.

### The Thromboplastin Generation Test (TGT)

In principle, this two-stage test<sup>7,10</sup> measures the amount and the rate of formation of prothrombinase via the intrinsic pathway (Fig. 33-5). The essential factors are provided by three reagents (Table 10-2, page 411): (1) *serum*, which contains all factors not consumed during coagulation (factors XII, XI, IX, and X); (2) *adsorbed plasma*, which contains factors V and VIII, and variable amounts of factors XII and XI, but no factor X or IX; and (3) *a source of platelet factor*

3, which may be a suspension of the patient's platelets or a platelet substitute. Both serum and the plasma are activated by glass contact and by dilution during preparation of the reagents.

The test is performed in two stages. In the first stage, prothrombinase formation is initiated by the addition of  $\text{Ca}^{++}$  to a mixture of the three reagents (reaction mixture). In the second stage, the prothrombinase formed is assayed by adding a portion of the reaction mixture to normal plasma (substrate plasma) which contains normal amounts of prothrombin and fibrinogen. The prothrombinase content of the reaction mixture, serially determined in this manner, increases with time, and within three to five minutes reaches a maximal level (substrate clotting time from 8 to 15 seconds).

If prothrombinase formation is deficient,

the abnormality can be localized to one or more of the three reagents by substituting control reagents. Results of the test (Table 33-2 and Fig. 33-6) usually are expressed in terms of the reagent found to be abnormal, i.e., serum "defects" (presumptive for deficiencies of factor IX or factor X) or plasma "defects" (presumptive for deficiencies of factor V or factor VIII). In the case of factors XI and XII, an abnormality may be present in both plasma and serum, or in serum alone, and usually is most prominent when both reagents are derived from the patient. The TGT usually gives abnormal results if the level of any essential factor is below 10% of normal,<sup>61</sup> and is thus less sensitive than the PTT in detecting the mildly affected patient. The factor V which is normally adsorbed by platelets (platelet factor 1) may minimize or normalize the plasma "defect" seen in

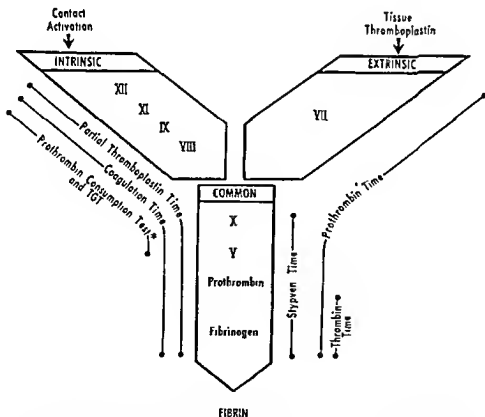

Fig 33 5 The interpretation of common screening tests of blood coagulation \* Platelet factor 3 also is required for normal prothrombin consumption

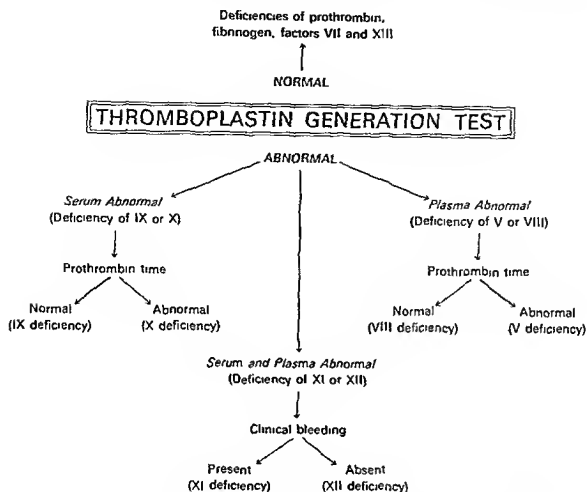

Fig 33-6. The utility of the thromboplastin generation test together with the prothrombin time in the diagnosis of hereditary coagulation disorders. Factor XII or factor XI deficiency may produce either a combined serum and plasma abnormality or a serum abnormality alone.

factor V deficiency if platelets are used rather than artificial substitutes. Abnormal values for TGT may also be caused by various inhibitors of coagulation ("circulating anticoagulants") (Chapter 38). The test is unaffected by deficiencies of prothrombin, fibrinogen, factor VII, and factor XIII.

The TGT can reliably differentiate between the two commonest forms of hemophilia, i.e., hemophilia A and hemophilia B, and does not require plasma from patients with known deficiencies. It is of limited value in the more complex acquired abnormalities of coagulation. Essential reagents are available commercially,<sup>46</sup> but the TGT is still relatively complex and time-consuming. A simplified thromboplastin screening test has been developed.<sup>73</sup>

When the test is used to measure platelet factor 3, platelet suspensions are required, but platelet substitutes save considerable time and are recommended for routine use.

### Related Methods

Although the coagulation time may be normal when only small amounts of prothrombinase are produced, a large amount of unconverted prothrombin will remain in the serum, i.e., prothrombin will not have been normally utilized or consumed. The quantitative measurement of residual prothrombin in serum after a standard interval is thus an indirect measure of the amount of prothrombinase formed, and is the essence of the various prothrombin consumption tests. These

tests measure the same factors as does the TGT, ie, those required for prothrombinase production via the intrinsic pathway (factors XII, XI, IX, VIII, X, and V) (Fig. 33-5). Although more sensitive than the clotting time in that it is abnormal when any of the essential factors are below 2 or 3% of normal,<sup>123</sup> the prothrombin consumption test is less sensitive than either the TGT or the PTT and, like the coagulation time, fails to detect mildly affected patients. Prothrombin conversion is incomplete and the prothrombin consumption test is abnormal in the presence of thrombocytopenia and in certain qualitative abnormalities of the platelets. The two-stage assay for prothrombin and prothrombin consumption<sup>140</sup> is an accurate and specific test, but is elaborate and time-consuming. Various simplified one-stage screening tests for prothrombin consumption have been devised, eg, the serum prothrombin time.<sup>112</sup> These tests may not be truly specific for residual prothrombin,<sup>71</sup> and are uninterpretable in the presence of deficiencies of factor VII or factor X.<sup>102</sup>

Various specialized tests for the factors involved in the contact phase of the intrinsic pathway have been devised, eg, the contact activation test,<sup>87</sup> the celite eluate test, and the celite-6-test<sup>95</sup> which may be valuable in defining an abnormality in the early stages of coagulation when naturally deficient plasmas are not available.

### Assay of Plasma Fibrinogen

Several accurate methods are now available for the quantitative assay of plasma fibrinogen, a measurement of increasing clinical importance which is now available in most laboratories.<sup>57</sup> Fibrinogen usually is converted into fibrin, which is quantitated by gravimetric, nephelometric,<sup>52</sup> or chemical<sup>115</sup> methods. Immunologic<sup>54</sup> and precipitation<sup>109</sup> methods have also been described. Methods which measure coagulable protein<sup>115</sup> are generally the most reliable. Precipitation methods may overestimate the fibrinogen level in intravascular coagulation (DIC),<sup>108</sup> and in the presence of certain anti-

biotics.<sup>93a</sup> Marked differences between the fibrinogen levels obtained by various methods are seen in the hereditary dysfibrinogenemias (Chapter 37).

### Related Methods

In determination of the plasma thrombin time,<sup>62,77</sup> pre-formed thrombin is added to plasma, and the time required for clot formation thus measures the rate at which fibrin is formed (Fig. 33-5). The time is prolonged when the fibrinogen level is below 100 mg/dl, but is unaffected by the levels of any of the other coagulation factors. It is prolonged by heparin and by abnormal amounts of other antithrombins. The thrombin time is technically simple, can be performed quickly, and is valuable, particularly in the diagnosis of DIC.

Screening "kits" for the detection of hypofibrinogenemia are available commercially and are widely used.<sup>122</sup>

### Tests for Intravascular Coagulation and Fibrinolysis ✓

The plasma euglobulin fraction contains plasminogen activators, plasminogen, any active plasmin present, and fibrinogen. Most of the antiplasmins remain in the "pseudoglobulin" supernate. The rate of lysis of a fibrin clot prepared from the euglobulin fraction (the euglobulin clot lysis time)<sup>138</sup> thus provides a means of measuring fibrinolysis in the absence of its inhibitors, and measures mainly the activity of plasminogen activators.<sup>102</sup> It is the most simple and rapid test yet devised for the detection of accelerated fibrinolysis.

Moderate concentrations of epsilon-amino caproic acid (EACA) ( $4 \times 10^{-4}$  M) inhibit plasminogen activators but not free plasmin (Chapter 10). Thus, a shortened euglobulin lysis time in the presence of such concentrations of EACA indicates the presence of free plasmin, eg, in fibrinogenolysis (Chapter 38). Fibrinolysis in heated fibrin plates<sup>3</sup> also measures free plasmin, since plasminogen activators are thermolabile.

The rate of whole blood clot lysis is a gross measurement of fibrinolysis, and its determination requires only the incubation and observation of a blood clot, eg, one of the samples obtained for a clotting time. If very rapid, whole blood clot lysis may be of diagnostic significance, but otherwise the time required for lysis, which normally is in excess of 24 hours, is usually too long to be of diagnostic help. Neither the euglobulin clot lysis time nor the whole clot lysis time is interpretable in the presence of severe hypofibrinogenemia, and may be normal in DIC as a result of plasminogen depletion.

The serial thrombin time provides an indirect assessment of the proteolytic effects of plasmin, but it is also abnormal in hypofibrinogenemia and in the presence of antithrombins such as fibrin degradation products.<sup>32</sup>

Tests for fibrinolysis and assays for individual components of the fibrinolytic enzyme system, including plasminogen activators, plasminogen, free plasmin, and antiplasmins, have been perfected<sup>130</sup> (page 432). These are largely research tools, but may be of diagnostic value in some cases of DIC and fibrinolysis.

Fibrin-fibrinogen degradation products (FDP) are protein fragments of various sizes which result from the proteolytic action of plasmin on fibrin or fibrinogen (Fig. 10-8, page 437). They are commonly present in DIC and fibrinolysis and are of considerable diagnostic significance. Quantitative assays for these fragments based on techniques such as red cell hemagglutination inhibition,<sup>89</sup> staphylococcal agglutination,<sup>80</sup> and immunodiffusion<sup>114,132</sup> (page 436) have been described. Most of these methods are rather time-consuming. Tests for FDP employing commercial reagents have also been described.<sup>89,114</sup>

Certain FDP are potent antithrombins which may prolong the thrombin time even when the fibrinogen level is above 100 mg/dl. The thrombin time obtained on a mixture of equal parts of normal plasma and patient's plasma will be normalized if the prolongation is due to fibrinogen deficiency,

but will remain abnormal if due to the presence of antithrombins such as FDP. This modification of the thrombin time ("corrected" thrombin time)<sup>24,62</sup> may thus be used as an indirect indicator of the presence of FDP; while quite nonspecific, the test is valuable primarily because it can be performed quickly.

Unpolymerized fibrin monomers (page 429) are commonly present in the blood in DIC. Various techniques ("paracoagulation" techniques) for demonstrating such monomers have been described. These range from the ethanol gelation test,<sup>28</sup> which is relatively insensitive, to various protamine gelation techniques,<sup>58,95,120</sup> which are highly sensitive but relatively nonspecific.<sup>44</sup> Of apparently similar significance are "cryofibrinogens" (page 1221) which may be demonstrated in some cases of DIC.

### Bioassays for Coagulation Factors

Bioassays for coagulation factors are usually based on the familiar screening and confirmatory tests, eg, the prothrombin time, partial thromboplastin time, and thromboplastin generation test. In principle, the extent to which an unknown sample corrects the abnormality in a plasma with a known deficiency is assumed to be proportional to the content of the deficient factor in the sample. The results are usually expressed as "percent of normal" which, depending on the exact method employed, normally ranges from 50 to 200%. The limitations and variables involved in such bioassay systems are considerable and have been discussed at length.<sup>10,62,75,81,116</sup>

Although there is no general agreement regarding the relative merits of one- and two-stage methods,<sup>6</sup> one-stage methods for factors VIII and IX which are based on the partial thromboplastin time and employ substrate plasma from patients with severe hereditary deficiencies of these factors have proved satisfactory in most laboratories, and are somewhat simpler to perform than comparable two-stage methods based on the thromboplastin generation test. However, the

availability of deficient plasma from patients often poses a major problem, and, as a consequence, methods have been developed which do not depend on natural substrates. These include techniques for the assay of prothrombin,<sup>106,140</sup> factors V,<sup>62,78</sup> VII and X combined,<sup>105</sup> and factors VIII,<sup>53</sup> IX,<sup>129</sup> X,<sup>42</sup> and XI.<sup>74</sup>

### *Tests for Inhibitors of Coagulation*

#### *(the "Circulating Anticoagulants")*

Abnormalities in any test of coagulation, if due to deficiency of an essential factor, will be corrected by the addition of small amounts of normal plasma or blood. If the abnormality is due to one of the various inhibitors of coagulation rather than a deficiency, the opposite is true, ie, small amounts of the patient's plasma will impair coagulation in normal samples. This is the essence of all tests for inhibitors, most of which are based on common screening tests, eg, the plasma recalcification time, the partial thromboplastin time,<sup>62</sup> the thromboplastin generation test.<sup>10,62</sup> The test system must often be adapted to the particular type of inhibitor (page 1208). The presence of exogenous heparin may be confirmed by means of various protamine neutralization tests.<sup>24,62</sup>

### *Automated Methods*

A variety of instruments have been developed which automatically detect the end point clotting time, and are helpful in the performance of the one-stage screening tests, eg, the prothrombin time and the partial thromboplastin time.<sup>91,122a,137</sup> Totally automated methods for performing these tests are being evaluated.<sup>2</sup>

The thromboelastograph is an instrument that demonstrates changes that occur during blood coagulation and fibrinolysis, and has been used extensively by some investigators. Different "coagulograms" are described in association with various bleeding disorders and hypercoagulable states.<sup>41,102</sup>

## **Initial Laboratory Approach**

### **The Utility of Screening Tests**

The initial laboratory study of the bleeding patient should be guided by the information obtained from the clinical evaluation. However, the routine use of a small battery of screening tests has merit in many cases, since it serves to direct the course of further study and usually saves time. It is generally agreed that the most essential information can usually be obtained from four tests summarized in Table 33-3, which, in view of their availability, simplicity, and low cost, are admirably suited to serve as "primary" screening tests. The platelet count and the bleeding time together provide the most reliable and reproducible tests of the vascular and platelet phases. The partial thromboplastin time measures all of the coagulation factors involved in the intrinsic and common pathways (Fig. 33-5) and is generally accepted as the best single screening test for disorders of blood coagulation. When supplemented with the plasma prothrombin time, which assesses the extrinsic as well as the common pathway, the abnormality can usually be localized to one of the three pathways and the factors involved therein (Fig. 33-5 and Table 33-3). Together, these four tests will thus provide a "presumptive diagnosis." This can then be further clarified by the confirmatory methods summarized in the following section. The definitive laboratory diagnosis of individual bleeding disorders is covered in Chapters 34 to 39, inclusive.

### **Confirmatory Tests**

#### **Thrombocytopenia**

Thrombocytopenia, like anemia, is a symptom and not a diagnosis. It is the most common of the acquired platelet disorders whereas hereditary forms are rare. Additional laboratory tests usually are not indicated merely to confirm the presence of thrombocytopenia (Table 33-3, A). The bleeding time, clot retraction, and the results of the

Table 33-3. The Presumptive Diagnosis of Common Bleeding Disorders by Means of

Platelet Count	Bleeding Time	Partial Thromboplastin Time	Prothrombin Time	"Presumptive Diagnosis"	Common Causes	
					Hereditary	Acquired
A Decreased	Prolonged	Normal	Normal	Thrombocytopenia	Aldrich syndrome (p 1127)	ITP (p 1075) drugs (p 1092) other secondary forms
B Normal or elevated	Prolonged	Normal	Normal	Disorder of platelet function	Thrombasthenia (p 1119) Deficient release reaction (p 1123)	Drugs (p 1128), uremia (p 1129) dysproteinemias (p 1130) thrombocythemia (p 1103)
C Normal	Prolonged	Prolonged	Normal	von Willebrand's disease (p 1179)		
D Normal	Normal	Prolonged	Normal	Coagulation abnormality in intrinsic pathway	Hemophilia A (p 1161) or B (p 1172) Deficiency of factors XI (p 1173) and XII (p 1179)	Inhibitors (p 1208)
E Normal*	Normal	Prolonged	Prolonged	Coagulation abnormality in common or multiple pathways	Deficiency of factors V, X (p 1178) prothrombin and fibrinogen dysfibrinogenemias (p 1174)	Liver disease (p 1205), vitamin K deficiency (p 1201), intravascular coagulation (p 1211), fibrinogenolysis (p 1224)
F Normal	Normal	Normal	Prolonged	Coagulation abnormality in extrinsic pathway	Deficiency of factor VII (p 1178)	
G Normal	Normal	Normal	Normal		Deficiency of factor XIII (p 1176) Telangiectasia (p 1144)	Allergic purpura (p 1136), scurvy (p 1150), drugs (p 1142), autoerythrocyte sensitization (p 1151)

\*May be abnormal in acquired disorders which produce deficiencies of multiple coagulation factors

prothrombin consumption test and the tourniquet test will yield abnormal values in the presence of significant thrombocytopenia. However, none of these tests is as accurate or reproducible as the platelet count, nor do they correlate any better than does the platelet count with the severity of bleeding in patients with thrombocytopenia. The differential diagnosis of thrombocytopenia is discussed at length in Chapter 34.

### Qualitative Disorders of Platelet Function

A prolonged bleeding time in the presence of a normal number of platelets and normal coagulation tests (Table 33-3, B) is presumptive evidence of a disorder of platelet function. Hereditary forms are uncommon, but bleeding due to platelet dysfunction may be an important complication in patients with various acquired disorders, eg, uremia. Commonly available confirmatory tests provide little ancillary information regarding platelet function. Tests of prothrombin consumption frequently yield abnormal values as a consequence of deficient activity of platelet factor 3. Deficient clot retraction suggests thrombasthenia, a very rare disorder. Various morphologic abnormalities of the platelets may be seen. Strikingly large platelets are characteristic of certain hereditary disorders, eg, the Bernard-Soulier syndrome (page 1126). A markedly elevated platelet count suggests hemorrhagic thrombocythemia and related disorders (page 1103).

Definitive methods for the study of these disorders are very time-consuming and technically difficult (Chapter 33). The absence of platelet aggregation by ADP, collagen, and epinephrine is characteristic of thrombasthenia (page 1119). Deficient collagen and epinephrine-induced aggregation despite normal ADP-induced aggregation are found in association with various disorders of the release reaction, eg, hereditary deficiency of storage nucleotides, uremia, aspirin ingestion. Disordered platelet function is discussed in Chapter 35.

### von Willabrand's Disease

This disorder is the result of an abnormality in "primary" hemostasis combined with mild to moderate deficiency of factor VIII (Chapter 37). In the typical case, the "primary" screening tests reveal a prolonged bleeding time and a prolonged partial thromboplastin time (Table 33-3, C). In many of these patients, only the bleeding time is abnormal, and in others there may be no detectable abnormalities. Furthermore, the results of all of the laboratory tests tend to fluctuate from time to time. The coagulation time and the results of the prothrombin consumption test may be abnormal if factor VIII deficiency is severe, but usually are normal. Useful confirmatory tests include measurements of ristocetin-induced platelet aggregation, in vitro platelet retention in glass-bead columns, and demonstration of "new" factor VIII synthesis following plasma infusions (page 1180). The last-named test is difficult to reproduce and is cumbersome.<sup>113</sup> In many cases, the diagnosis depends on repeated observations over a period of time.

### Disorders of the Intrinsic Pathway of Coagulation

Disorders characterized by a prolonged partial thromboplastin time and a normal prothrombin time (Table 33-3, D) include hemophilia A and hemophilia B, and deficiencies of factors XI and XII. These together comprise over 80% of all hereditary coagulation disorders (Chapter 37). Factor XII (Hageman factor) deficiency can be readily excluded since it is not associated with bleeding. The thromboplastin generation test provides the most simple way to distinguish between the remaining three, and, together with the prothrombin time, affords what is essentially a specific diagnosis (Fig. 33-5). The coagulation time and results of the prothrombin consumption test depend on the severity of the deficiency, and should never be relied upon to exclude these disorders

since the results of both tests will be abnormal only in severely affected patients.

In deficiencies of factors XI, XII, and possibly Fletcher factor deficiency (page 1183), the results of the activated partial thromboplastin time may be the same as those obtained with the nonactivated method, and, when silicone-coated tubes are used, the coagulation time and the results of the prothrombin consumption test may be normal, in contrast to the gross abnormalities found when glass tubes are used.

Acquired coagulation disorders are seldom associated with a prolonged PTT and a normal prothrombin time. Important exceptions are the various inhibitors or circulating anticoagulants (Chapter 38). A slight prolongation of the partial thromboplastin time together with a normal prothrombin time is frequently the result of a poorly collected blood sample, and is not uncommon in patients with liver disease.<sup>130</sup>

### Disorders of the Common Pathway of Coagulation

In a patient with a hereditary disorder, prolongation of the PTT and the prothrombin time indicates a deficiency of one of the factors in the common pathway, ie, either factor X, factor V, prothrombin, or fibrinogen (Table 33-3, E). Such isolated deficiencies are exceedingly rare. On the other hand, in many of the most common acquired coagulation disorders, deficiencies of one or more of these factors are associated with additional abnormalities in the intrinsic and extrinsic pathways, eg, vitamin K deficiency, intravascular coagulation. As a consequence, a prolonged prothrombin time always suggests an acquired disorder, and usually is associated with a complex abnormality involving multiple pathways, eg, DIC.

When confronted with this combination of findings, the first step should be to exclude or identify an abnormality in the thrombin-fibrinogen reaction (Fig. 33-7). This may be accomplished by determination of the thrombin time and fibrinogen assays. The most helpful ancillary procedures are the platelet

count, examination of the blood smear for schistocytes, the thrombin time, the fibrinogen level, the euglobulin lysis time, and tests for FDP. The laboratory diagnosis of DIC is summarized in Chapter 38.

Hereditary disorders which are associated with a prolonged thrombin time and low fibrinogen levels include hereditary afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia (page 1174).

Hereditary deficiencies of factor V, factor X, and prothrombin can be distinguished from one another by simple correction tests<sup>37,102</sup> and by the thromboplastin generation test (Figs. 33-6 and 33-7).

### Disorders of the Extrinsic Pathway of Coagulation

A prolonged prothrombin time and a normal partial thromboplastin time (Table 33-3, F) suggest an isolated deficiency of factor VII, which is very rare. Since factor VII is essential only in the tissue-activated extrinsic pathway of coagulation, the coagulation time, the Stypven time, and thromboplastin generation are normal in this disorder.

### Disorders in Which Results of "Primary" Screening Tests Are Normal

The screening tests usually yield normal results in patients with bleeding disorders due to vascular abnormalities (Tables 33-3, G and 33-4). Laboratory techniques for the study of these disorders are crude or nonexistent. A slight prolongation of the bleeding time or a positive reaction to the tourniquet test may be obtained in some cases, but the diagnosis usually is made from the associated clinical findings which are often characteristic, eg, the skin lesions of hereditary hemorrhagic telangiectasia, allergic purpura, scurvy, senile purpura. A positive reaction to a specific skin test may confirm the diagnosis of autoerythrocyte sensitization and related disorders (Chapter 36). The results of screening tests also are normal in factor XIII (fibrin stabilizing factor) deficiency (Chapter 37), a disorder in which the diagnosis is made by the demon-

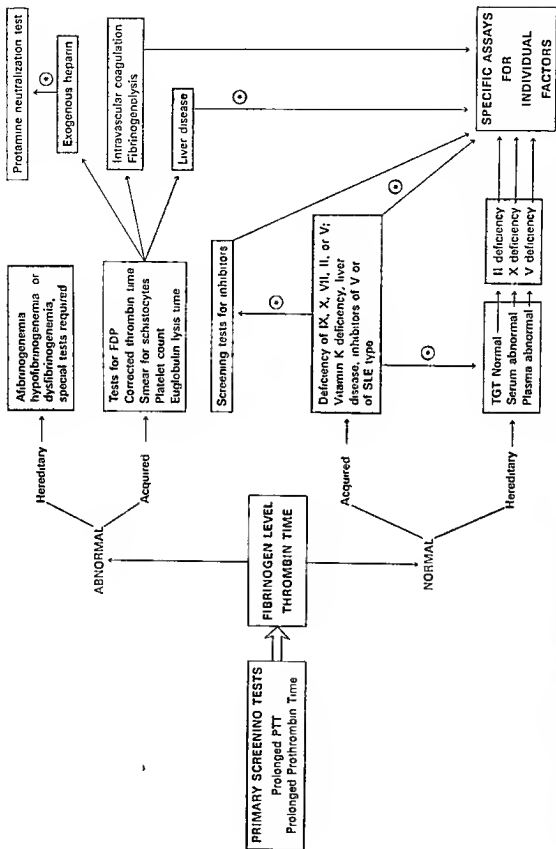

Fig. 33-7. Flow sheet for laboratory evaluation of coagulation disorders of common or multiple pathways. Tests are indicated in solid blocks; presumptive diagnoses in shaded blocks. Only the most common disorders are included. Asterisks denote disorders in which the clinical picture is usually clear-cut and in which the ancillary laboratory studies indicated by arrows are seldom required.

stration of characteristic clot solubility in urea or other protein solvents.<sup>62</sup>

Although abnormal in the typical case, the results of screening tests may be normal or equivocal in patients with mild coagulation disorders, including heterozygous carriers, in patients with certain disorders of platelet function, and in those with mild forms of von Willebrand's disease. Various as yet undefined abnormalities of the contact phase of coagulation also may not be detected in the "primary" screening tests.

Patients with a significant bleeding history, in whom the results of detailed studies of hemostasis and blood coagulation are normal, constitute a larger problem. Such "bleeders" are not uncommon, and probably suffer from disorders of hemostasis which cannot be detected by presently available methods. These patients should always be managed with great care, and it should be emphasized that a clear-cut history of bleeding is always more significant than negative laboratory data.

Trauma may be denied in the "battered-child" or "battered-wife" syndrome, and may be self-inflicted in psychotic or neurotic patients.

The value of routine screening tests prior to surgical procedures has been debated for years. It is clear that the coagulation time, estimates of clot retraction, whole clot lysis time, and the tourniquet test are of little value, and very few abnormalities will be

detected by even the more sensitive screening methods in patients with a completely negative history and normal findings on physical examination. To the contrary, "routine" pre-operative laboratory screening is of great value in certain "high-risk" patients who suffer from disorders which are known to predispose to unexpected postsurgical bleeding,<sup>38</sup> even from relatively limited biopsy procedures. Important in this category are patients with liver disease, biliary obstruction, renal disease particularly if complicated by azotemia, myelofibrosis, and those with the dysproteinemias. To this list should be added all patients scheduled to undergo procedures involving the use of extracorporeal circulatory devices.

## Laboratory Evaluation in the Newborn

Laboratory investigation of hemostasis and blood coagulation in the neonate and infant differs from that outlined above in several respects. Firstly, the quantity of blood which can be obtained is limited, and the venipuncture is frequently difficult. Various micro-techniques, and methods which employ capillary blood<sup>40b,47,62,66,93</sup> have been devised to circumvent this problem. Secondly, in terms of adult norms, the results of most tests vary widely and often are abnormal even in healthy full-term infants. This presumably is the result of deficiencies of the vitamin K-dependent factors, and additional "physiologic" abnormalities which have been demonstrated in the contact phase and in the thrombin-fibrinogen reaction.<sup>1,101</sup> The prothrombin time may be prolonged, but is often normal if vitamin K is administered to the infant or mother.<sup>1</sup> Abnormalities of the thrombin time, the partial thromboplastin time, and in the results of thromboplastin generation test are common, and may persist for months.<sup>101</sup> These abnormalities are more pronounced in the premature than in the full-term infant, and in extent are inversely proportional to gestational age and birth weight.<sup>26</sup> The levels of fibrinogen and factors V and VIII are usually normal.<sup>1</sup> Tests for

**Table 33-4. Disorders in Which the Results of the "Primary" Screening Tests May Be Normal**

- 1 von Willebrand's disease
- 2 Mild hereditary coagulation disorders, particularly factor XI deficiency
- 3 Heterozygous carriers of hereditary coagulation disorders
- 4 Factor XIII (fibrin stabilizing factor) deficiency
- 5 Mild, as yet undefined, abnormalities in the contact stage of coagulation
- 6 Some forms of dysfibrinogenemia
7. Disordered platelet function particularly deficient release reaction
- 8 Hereditary hemorrhagic telangiectasia
- 9 Allergic and "vascular" purpuras ✓

FDP and the euglobulin lysis time may be unreliable if carried out on cord blood. Significant abnormalities of platelet aggregation and of other platelet function tests may be seen in normal neonates,<sup>94</sup> but the platelet count in term infants as well as in thriving prematures approaches adult norms.

## Thrombocytopenia

Purpura in association with pestilential fevers was described by Hippocrates and later writers, but it was not until the 16th century (Lusitanus) and the early part of the 17th century (La Rivière) that purpura in the absence of fever was recognized.<sup>57</sup> Werlhof in 1735 distinguished "morbus maculosus hemorrhagicus" as a separate entity, and Willan in 1808 classified purpura under the headings (1) simplex, (2) haemorrhagica, (3) urticans, and (4) contagiosa, thus separating the types later described by Schönlein (1829) and Henoch (1868) which are now known by their names (Chapter 36). The marked diminution in "hematoblasts" (platelets) in "purpura hemorrhagica" was recognized by Krauss (1883) and by Denys (1887). Hayem (1895) noted the non-retractility of the blood clot, and Duke (1912) demonstrated the prolonged bleeding time. Abnormal capillary fragility was observed by writers in different countries ("le signe du lacet," Grocco-Frugoni's sign, the Rumpel-Leede phenomenon, Hess' capillary resistance test).<sup>51</sup>

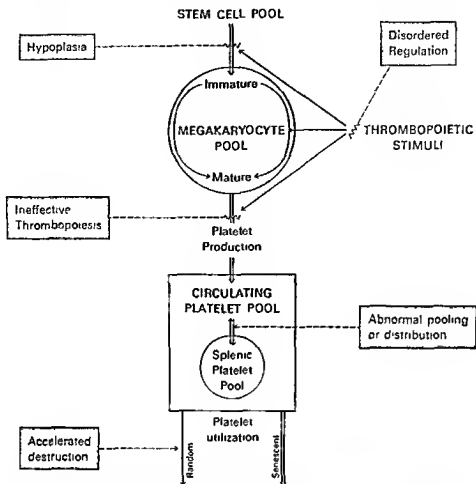

Fig 34-1 The pathophysiology of thrombocytopenia. A simplified diagram of the biodynamics of the megakaryocyte-platelet system is indicated in solid lines. The mechanisms by which pathologic processes (shaded blocks) produce thrombocytopenia are indicated in dashed lines.

### Pathophysiology

Thrombocytopenia may be defined as a subnormal number of platelets in the circulating blood. It is the most common cause of abnormal bleeding. The pathophysiology of thrombocytopenia is quite similar to that of anemia, but the latter is better understood. Thus, despite the number and diversity of disorders that may be associated etiologically, thrombocytopenia results from only three processes. These are: (1) deficient platelet production; (2) accelerated platelet destruction; and (3) abnormal distribution or pooling of the platelets within the body (Fig. 34-1).<sup>395</sup> The changes in the basic parameters

of thrombopoiesis that are characteristic of each of these processes are summarized in Table 34-1.

*Accelerated platelet destruction* is the commonest cause of thrombocytopenia. It leads to stimulation of thrombopoiesis, and consequently to an increase in the number, size, and rate of maturation of the precursor megakaryocytes (Fig. 34-1). When the rate of platelet destruction exceeds this compensatory increase in platelet production, thrombocytopenia develops. "Compensated" platelet destruction without thrombocytopenia may also occur,<sup>397a</sup> eg, in patients with prosthetic heart valves<sup>415</sup> and in patients with ITP following splenectomy.<sup>45</sup>

Table 34-1. Thrombokinetetic Patterns in Various Forms of Thrombocytopenia

Measurement	Decreased Production			
	Hypoproliferation or Hypoplasia*	Ineffective Thrombopoiesis†	Accelerated Destruction‡	Abnormal Pooling
Total megakaryocyte mass§	Decreased	Increased	M increased	Var increased
Megakaryocyte number	Decreased	M increased	Increased	Var increased
Megakaryocyte volume	Increased	Normal or Var decreased	Increased	Var increased
Platelet turnover rate or production rate	Decreased	Decreased	Increased	Var increased
Total platelet mass	Decreased	Decreased	Decreased	? Normal
Splenic platelet pool	Decreased	Decreased	Decreased¶	Increased
Platelet survival	Normal	Var shortened	Shortened	Var shortened

KEY Var = variably M = markedly

\*Includes myelophthisic processes

†Mainly in megaloblastic hematopoiesis component of accelerated destruction present in some cases

‡Minor component of "ineffective" thrombopoiesis present in some cases

§Equated to "total" thrombopoiesis

|| Equated to "effective" thrombopoiesis

¶Not representative of sequestered antibody-sensitized platelets

Based on the work of Harker et al.<sup>45,194,195,196</sup> The data upon which this table is based are tentative since techniques for the study of platelet kinetics have been developed only recently

Platelet destruction may result from both "intracorporeal" and "extracorporeal" abnormalities. Intracorporeal defects are rare, but have been demonstrated in certain forms of hereditary thrombocytopenia, eg, the Wiskott-Aldrich syndrome (page 1127).<sup>336,396</sup> In such disorders, the survival of affected platelets is shortened both in the patient and in normal recipients. More frequently, platelet destruction is the result of extracorporeal factors, various immunologic phenomena being the most common. Platelets injured by either intracorporeal or extracorporeal processes usually are removed from the circulation by the spleen, liver, and reticuloendothelial system.

Platelet utilization in intravascular thrombi or on damaged endothelial surfaces is another cause of thrombocytopenia. This occurs in diffuse intravascular coagulation (page 1211), and in thrombotic thrombocytopenic purpura and other microangiopathic processes (Chapter 28).

Deficient platelet production may result from any of a number of processes. Those that depopulate the stem cell or megakaryocyte compartments are the most common, eg, marrow injury by myelosuppressive drugs or irradiation, aplastic anemia (Chapter 56).

Deficient platelet production also may be the consequence of disordered proliferation within a precursor compartment of normal or even increased size. For example, in disorders characterized by megaloblastic hematopoiesis, hypertrophy of the precursor compartment occurs in response to thrombopoietic stimuli, but thrombopoiesis is "ineffective" and platelet production is insufficient. Rarely, abnormalities of those processes that normally regulate thrombopoiesis appear to underlie deficient platelet production, eg, deficiency of "thrombopoietin," cyclic thrombocytopenia (page 1098).

Abnormal pooling or abnormal in vivo distribution of an essentially normal total platelet mass may produce thrombocytopenia. This is seen in the various disorders associated with splenomegaly (Chapter 45), in which platelet production is normal or even increased, but the majority of the platelets are sequestered in the vastly enlarged extravascular splenic pool.

### Classification

All disorders in which purpura was associated with thrombocytopenia were at one time considered to be a single entity, and various

Table 34-2. Etiologic Classification of Thrombocytopenia<sup>a</sup>

## I PRIMARY VARIETIES

A *Idiopathic thrombocytopenic purpura (ITP)*B *Hereditary forms (Table 34-6)*C *Miscellaneous (congenital megakaryocytic thrombocytopenia cyclic thrombocytopenia, tidal platelet dysgenesis deficiency of thrombopoietin)*

## II SECONDARY OR SYMPTOMATIC VARIETIES

names were applied, such as purpura hemorrhagica, Werlhof's disease, morbus maculosus Werlhofi, hemogenia, hemogenic syndrome,<sup>107</sup> thrombocytolytic purpura. When it was found that thrombocytopenia may result from a large variety of definable causes, thrombocytopenia in such disorders was termed "secondary" or "symptomatic" in contradistinction to "essential," "primary," or "idiopathic" forms. Even though the terms

"primary" and "idiopathic" have no real meaning in modern medicine, this distinction has proved to be clinically useful, and provides the basis for the etiologic classification of thrombocytopenia presented in Table 34-2.

A classification of thrombocytopenia based on the above-described pathophysiologic criteria is presented in Table 34-3. Such a classification must be regarded as tentative, since

**Table 34-3. Pathophysiologic Classification of Thrombocytopenia**

- I DEFICIENT THROMBOPOIESIS ✓
  - A *Hypoplasia or suppression of megakaryocytes*
    - 1 Chemical and physical agents (Table 34-5, Table 56-2, page 1746)
    - 2 Idiopathic aplastic anemia and related disorders (congenital megakaryocytic hypoplasia Fanconi syndrome others)
    - 3 Myelophthisic processes, some viral infections
  - B *Ineffective thrombopoiesis* (disorders due to deficiency of vitamin B<sub>12</sub> or folic acid paroxysmal nocturnal hemoglobinuria some hereditary forms, others)
  - C *Disordered control mechanisms* (deficiency of thrombopoietin, tidal platelet dysgenesis cyclic thrombocytopenia)
  - D *Miscellaneous* (many hereditary forms)
- II ACCELERATED PLATELET DESTRUCTION UTILIZATION OR LOSS
  - A *Due to immunologic processes*
    - 1 Autoantibodies (ITP drug induced antibodies [Table 34-5] various hemolytic anemias, SLE, lymphoreticular disorders hyperthyroidism, others)
    - 2 Isoantibodies (due to fetomaternal incompatibility, post-transfusion)
    - 3 Other immunologic processes (allergies erythroblastosis fetalis anaphylactic reactions, immune complexes)
  - B *Due to nonimmunologic processes*
    - 1 Diffuse intravascular coagulation (Table 38-3, page 1212) Kasabach-Merritt syndrome (giant hemangioendotheliomas), many infections
    - 2 Microangiopathic processes (thrombotic thrombocytopenic purpura, prosthetic cardiac valves, many others)
    - 3 Miscellaneous (some infections, massive transfusions and exchange transfusions, extracorporeal circulatory devices fibrinogenolysis, Ristocetin, some hereditary forms)
- III ABNORMAL PLATELET DISTRIBUTION OR POOLING
  - A *Disorders of the spleen* (neoplastic, congestive, infiltrative, infectious, of unknown cause [Table 45-1, page 1407])
  - B *Hypothermic anesthesia*

presently available methods for studying thrombopoiesis are relatively crude, and in many disorders multiple pathogenetic factors may simultaneously or sequentially play a role in the production of thrombocytopenia.

The following discussion will utilize the most suitable nosologic features of both the etiologic and the pathophysiologic classifications, since neither alone is entirely satisfactory.

## Immunologic Platelet Destruction

### Idiopathic Thrombocytopenic Purpura

#### Definition

The term "idiopathic thrombocytopenic purpura" (ITP) is usually employed to refer to instances of thrombocytopenia associated with no apparent exogenous etiologic factors, underlying diseases known to be associated with "secondary" thrombocytopenia having been excluded. The presence of a normal or increased number of megakaryocytes in the bone marrow has been observed so consistently that this finding is now widely accepted as an additional criterion for the diagnosis of ITP. ITP is thus a diagnosis of exclusion, and must be regarded as a syndrome that may arise in several different ways and one that undoubtedly encompasses a variety of fundamentally different disorders. Proposals to further restrict or broaden these admittedly vague diagnostic criteria, or to redefine the meaning of the term ITP<sup>4</sup> have not been widely accepted. This syndrome has been reviewed in detail.<sup>4,16,40,115,271,421</sup>

There are several differences between *acute ITP* and *chronic ITP*; these are of particular significance in the interpretation of data concerning the incidence of the disorder, its prognosis, and the results of therapy (Table 34-4). The differences may illustrate merely the wide spectrum of disorders that by definition are included in the syndrome, but many would now accept the view that acute ITP and chronic ITP are fundamentally different disorders.<sup>4,40</sup>

#### Incidence

ITP is more common than all secondary forms of thrombocytopenia combined.<sup>371</sup> The disorder occurs most frequently in children and young adults.<sup>112</sup> In 67% of a series

Table 34-4. Features of Acute and Chronic ITP

	Acute	Chronic
Peak age incidence	Children 2-6 years of age	Adults, 20-40 years of age
Sex predilection	None	3:1 ratio of female to male cases
Antecedent infection	Common 1-3 weeks prior to onset	Unusual
Onset of bleeding	Abrupt	Insidious
Hemorrhagic bullae in mouth	Present in severe cases	Usually absent
Platelet count	$< 20 \times 10^9/l$	$30-80 \times 10^9/l$
Eosinophilia and lymphocytosis	Common	Rare
Duration	2-6 weeks rarely longer	Months or years
Spontaneous remissions	Occur in 80% of cases	Uncommon; fluctuating course common

of 271 patients,<sup>14,33,137</sup> the disease appeared before the age of 21 years (Fig. 34-2). In a summary of 737 cases reported in the literature,<sup>421</sup> 45% of the patients were found to be 15 years of age or younger. It is well recognized that ITP occurs more frequently in females than in males.<sup>137</sup> The ratio in different series has ranged from 4:3 to 3:1.<sup>100, 125,344</sup> The condition seems to be uncommon among Negroes.<sup>137</sup>

These figures become more intelligible when cases are divided into acute and chronic types (Table 34-4). Thus, acute ITP is com-

monest in children two to six years old<sup>75,89</sup> and rarely may develop in the first year of life.<sup>126</sup> It is uncommon in adults, has no sex predilection, but does occur with a peak incidence during the fall and winter, thus paralleling the prevalence of upper respiratory tract infections.<sup>40</sup> Chronic ITP may be encountered in persons of all ages, but is relatively more common in those between puberty and 50 years of age. It occurs much more frequently in women than in men, a ratio of female to male patients of approximately 3:1 having been found repeatedly.<sup>421</sup>

Fig 34-2 Age and sex distribution of idiopathic thrombocytopenic purpura 66 cases in Salt Lake City<sup>19</sup> compared with 271 cases from New York,<sup>14</sup> Philadelphia<sup>33</sup> and Baltimore<sup>137</sup>

the "ITP factor" is indeed an antibody have met with limited success.<sup>26,478</sup> The *complement fixation test*, which has proved well suited to the study of drug-induced platelet autoantibodies and platelet isoantibodies, has yielded essentially negative results in ITP.<sup>115-478</sup> The presence of *platelet agglutinins* has been reported by several groups.<sup>47,49</sup> In one series, positive results were obtained in 100 out of 132 consecutive cases of ITP.<sup>49</sup> However, contradictory results have been obtained with this and related tests in different laboratories,<sup>49,371</sup> and it is probable that in many cases platelet agglutination represented an artefact, ie, platelet clumping by traces of thrombin in serum.<sup>56</sup> Experience with various direct and indirect *antiglobulin tests* has been similar; ie, initially enthusiastic reports were soon followed by inconsistent results.<sup>115,123,364,476,493</sup> Like platelet agglutination, this technique is relatively insensitive and is of questionable validity in ITP because of frequent falsely positive results.<sup>476</sup>

Preliminary results obtained with less conventional methods have been more encouraging. Measurements of platelet factor 3 "availability"<sup>197</sup> or the release of <sup>14</sup>C-5-hydroxytryptamine<sup>50a</sup> or <sup>51</sup>Cr-chromate from labeled platelets are sensitive indices of platelet injury by antibodies. With these methods ("immuno-injury" techniques), antibodies were detected in 65% of patients with ITP.<sup>61</sup> Such techniques are even more sensitive when platelets with an abnormal propensity to immunologic injury, such as those from patients with paroxysmal nocturnal hemoglobinuria, are used in the test system.<sup>2</sup> Despite the increased sensitivity of these methods, negative results were obtained in a significant number of patients with otherwise typical ITP, and positive results were obtained in those with many other conditions, eg, systemic lupus erythematosus (SLE), inflammatory disorders, lymphoreticular disorders.

Still other modifications, refinements, and immunologic systems have been described,<sup>4,44,78,231</sup> but a uniformly satisfactory serologic technique for demonstrating and quantifying the antibody that presumably is

present in ITP has yet to be described. It is probable that a blocking antibody is present in some patients with ITP<sup>475</sup> and that, in others, the platelets are injured by concentrations of antibody that are undetectable in vitro. The latter phenomenon has been clearly demonstrated in studies of well-defined isoantibodies and drug-induced autoantibodies, to be discussed below.

Various other processes may lead to platelet injury in ITP. The possible presence of cell-mediated immunologic processes was suggested by studies demonstrating the capacity of platelets from patients with chronic ITP to induce in vitro lymphocyte transformation,<sup>93</sup> and to enhance the uptake by lymphocytes of <sup>14</sup>C-labeled thymidine.<sup>140</sup> Studies demonstrating inhibition of leukocyte migration by autologous platelets in this disorder<sup>19</sup> provide additional support for this hypothesis, and further suggest the presence of a blocking antibody that may inhibit delayed hypersensitivity. These data led to the hypothesis that a fluctuating balance between cellular and humoral immunologic phenomena is the major determinant of platelet injury in ITP.<sup>19</sup>

A different immunologic phenomenon may be involved in the pathophysiology of the acute self-limited form of the disorder. The frequency with which acute ITP is associated with an antecedent viral infection and the characteristic latent period between the acute infection and the onset of thrombocytopenia have led to the suggestion that a viral antigen-antibody complex, rather than a platelet autoantibody, may be responsible for platelet sensitization and sequestration.<sup>304</sup> This mechanism is discussed further on page 1101.

### Role of the Spleen

The importance of the spleen in the pathogenesis of ITP is suggested by the therapeutic effectiveness of splenectomy in this disorder. In 1916, Kaznelson proposed that the spleen acts as a filter to remove platelets from the circulation,<sup>64</sup> a hypothesis that remains consistent with presently available data.

Despite the frequent use of terms such as "thrombocytolytic," there is little evidence that platelets are aggregated or "lysed" within the circulation in ITP.<sup>115</sup> Rather, the platelets are sensitized and then removed from the circulation. When <sup>51</sup>Cr-chromate-labeled isologous platelets are administered to patients with ITP, external scintillation counting reveals a rapid accumulation of radioactivity predominantly in the spleen.<sup>3</sup> Platelet phagocytosis by splenic leukocytes has been demonstrated *in vitro*.<sup>80</sup> The rate of splenic platelet sequestration is relatively slow in most cases, and in severe cases appeared to be limited mainly by the rate of splenic blood flow.<sup>3</sup> Preliminary evidence suggests that young platelets are preferentially sequestered in the spleen.<sup>480</sup> Hepatic sequestration of platelets has been documented in ITP, usually in patients with severe thrombocytopenia and markedly shortened platelet survival.<sup>3,45</sup> The administration of small amounts of plasma from patients with ITP to normal subjects produced mainly splenic sequestration, whereas larger amounts led to hepatic sequestration.<sup>116</sup> A similar pattern of sequestration was demonstrated when platelet antibodies were infused into animals.<sup>334</sup> These data suggest that the factors involved in the sequestration of platelets in ITP are quite similar to those that determine the sequestration of erythrocytes damaged by antibodies (Chapter 27). The value of measurements of *in vivo* platelet sequestration in predicting the outcome of splenectomy in ITP is discussed on page 1087.

Reticuloendothelial sequestration, including that which occurs in the spleen, is inhibited by corticosteroids and facilitated by estrogens.<sup>116,438</sup> An estrogen-induced increase in the rate of platelet sequestration in the spleen may explain the high incidence of ITP in women of childbearing age, and the frequency with which the disease appears or relapses at the menarche and during pregnancy.<sup>371</sup>

It has been suggested that the spleen also is important in ITP as a site of production of platelet antibodies.<sup>58,61,62</sup> An IgG globulin that acts as a platelet antibody has been ex-

tracted from spleens of patients with ITP,<sup>61</sup> and is synthesized by splenic cells in tissue culture.<sup>62</sup> Splenic tissue from patients with ITP produces more immunoglobulin than that of normal controls, and a significant percentage of that formed binds to homologous platelets.<sup>70</sup> The high levels of antibody within the spleen may favor sensitization of platelets.<sup>1</sup> Following splenectomy, the titer of platelet antibodies falls in some subjects.<sup>6</sup> Even though the spleen appears to be a site of antibody production, there is as yet little direct evidence that this is especially important in the pathophysiology of ITP.

### *Role of Impaired Thrombopoiesis*

The pathophysiologic role played by megakaryocyte damage or suppression in ITP remains unclear, despite a controversy that antedates the presently accepted immunologic theory by many years.<sup>28,39,119,491</sup> Evidence for such a process is largely indirect. Thus, the absence of platelet "budding" from megakaryocytes and the morphologic abnormalities of these cells which are commonly seen in ITP have been interpreted as evidence of a suppressive or injurious effect on the precursor cell. A different explanation for these changes seems more likely, however; ie, they are the result of accelerated platelet production in response to peripheral platelet destruction. Similar abnormalities are found in animals<sup>361</sup> and in man<sup>115</sup> rendered thrombocytopenic by thrombocytapheresis, and in various forms of thrombocytopenia caused by accelerated platelet destruction by nonhumoral processes, eg, hemangioendotheliomas, thrombotic thrombocytopenic purpura (Chapter 28), intravascular coagulation (Chapter 38).

In chronic ITP, a plasma globulin has been demonstrated on the surface of the megakaryocytes by means of immunofluorescent techniques.<sup>67,77,95</sup> This is not surprising since the platelet and the cytoplasm of its precursor are identical in most respects, including their antigenic structure.<sup>26,111,118,494</sup> It is conceivable that this antibody might impair platelet

production. Large doses of heterologous antibodies impair platelet production in animals,<sup>191</sup> and indirect evidence of impaired thrombopoiesis has been found in some patients with severe ITP.<sup>336</sup> Thrombokinetic studies suggest that in ITP, platelet production, although insufficient to balance the rapid rate of destruction, is nevertheless increased.<sup>181</sup> Thus, total megakaryocyte mass ("total" thrombopoiesis) and the platelet turnover rate ("effective" thrombopoiesis) were two to nine times normal in 16 cases.<sup>45</sup> A rough correlation between the severity of the thrombocytopenia and the rate of platelet production was demonstrated; in severely affected patients, platelet production approximated the maximal precursor response.<sup>45,390</sup>

In summary, it is probable that the antibodies present in ITP interact with the megakaryocyte, but the possibility of a minor component of deficient or ineffective thrombopoiesis cannot be excluded by presently available methods.

### Role of Vascular Injury

Various clinical observations have led to the widely accepted hypothesis that direct vascular injury is of pathogenetic importance in ITP. Thus, the severity of hemorrhage seldom correlates well with the platelet count, and bleeding often is more troublesome in ITP than in secondary thrombocytopenia of equal severity, eg, aplastic anemia. Furthermore, the administration of corticosteroids or splenectomy may restore the bleeding time to normal and diminish the severity of the bleeding manifestations before, or in the absence of, an increase in the platelet count. More direct evidence usually cited in support of this hypothesis<sup>6,34,69,122,129</sup> is unconvincing, and an alternative explanation for the findings described above is equally plausible; viz, the platelets made available by any slight increase in the balance between platelet production and destruction, although not sufficient to increase the circulating platelet count, may improve hemostasis.<sup>216</sup> Such a phenomenon may explain the cessation of bleeding that may follow platelet transfusions

in ITP even though there is no increase in the platelet count.

### Clinical Picture

In *acute ITP*, the onset of the disorder usually is sudden (Table 34-4). The frequency with which a history of antecedent infection precedes the onset of bleeding has been documented repeatedly.<sup>16,271</sup> In one series, such infections were noted within three weeks preceding the onset of ITP in 84% of the cases.<sup>75</sup> Common childhood exanthems and viral respiratory diseases are the most common; rarely, acute ITP has followed vaccination.<sup>263,299</sup> In *chronic cases*, the onset usually is insidious. A long history of mild hemorrhagic symptoms is commonly obtained from the patient, but a history of antecedent infection is uncommon.

Even though thrombocytopenia is likely to be marked, the clinical manifestations of acute ITP in children are rarely severe.<sup>43</sup> In the rare adult with the acute form of the disorder, however, hemorrhage and a fulminant course may be seen.<sup>4</sup> In chronic ITP, mild to moderate bleeding is the usual finding.

Fever of mild degree may be present, and the spleen tip is palpable in approximately 10% of the patients.<sup>57,371</sup> However, the spleen never extends more than 2 to 3 cm below the costal margin.<sup>341,371</sup>

The hemorrhagic manifestations in ITP are of the "purpuric" type (Table 33-1, page 1044), and the following description applies, with few exceptions, to thrombocytopenia of any etiology.

### Skin and Mucous Membranes

Spontaneous bleeding into the skin in the form of *petechiae* is characteristic. These lesions are minute, red hemorrhages that range in size from that of a pinpoint to that of a pinhead (Fig. 33-1, page 1045). They are flat, do not blanch on pressure (Table 36-2, page 1138), and appear and regress, often in crops, over a period of days. They are most conspicuous in areas of vascular stasis such as

the dependent portions of the body and areas subjected to constriction from girdles or stockings, and on skin surfaces over bony prominences, eg, the ankle. The presence of petechiae on the face and neck is unusual except as the result of coughing. The patient may confuse these characteristic lesions with freckles or a rash.

*Ecchymoses* may develop on any skin surface. In ITP, they are seldom associated with subcutaneous hematomas, and infrequently spread or dissect into deeper or adjacent structures. Large, purple, superficial ecchymoses may be seen, particularly on the back and thighs. Circular ecchymoses frequently surround even atraumatic venipuncture sites, but external bleeding from such sites is uncommon.

Attention has been called to the occasional association of chronic leg ulcers with ITP, but this is rare.<sup>139</sup>

*Hemorrhagic vesicles or bullae* may be seen inside the mouth and on other mucous surfaces. These lesions are particularly common in a form of acute thrombocytopenia known as *onychia*, and in acute thrombocytopenia due to drug-induced antibodies (page 1091). They probably are the result of severe acute thrombocytopenia, rather than a specific feature of any particular pathogenetic form.

*Gingival bleeding and epistaxis* are common. The latter usually responds for a time to conservative measures such as nasal packing or tamponade, often to recur again and again. Epistaxis may originate from lesions resembling petechiae in the nasal mucosa, but, in many subjects, discrete bleeding points cannot be identified. Such lesions also may be found in the mucous membranes of the throat and mouth, sometimes in the absence of cutaneous hemorrhage.

The *genitourinary tract* is a frequent site of bleeding. Menorrhagia may be the only symptom of ITP,<sup>371</sup> and may appear for the first time at puberty or even before. Rupture of the hymen may be followed by profuse hemorrhage. Hematuria also is a common symptom. The blood may come from the renal pelvis, the bladder, or the urethra. Bleeding into the kidney parenchyma is rare.

*Gastrointestinal bleeding*, manifested by melena or less frequently by hematemesis, may be an important feature of ITP.

### Central Nervous System

Intracranial hemorrhage is the most serious complication of ITP, but fortunately is rare. It occurs in 1% or less of the patients.<sup>18,75</sup> The hemorrhages usually are subarachnoid in location. They are often multiple and vary in size from petechiae to large extravasations of blood.<sup>74</sup>

Numerous small hemorrhages often are seen in the retina; subconjunctival hemorrhage is not uncommon.

### Bleeding Following Trauma

Excessive bleeding frequently follows tooth extractions, tonsillectomy, or other operations or injuries, and may first attract attention to ITP. In contrast to the hereditary coagulation disorders, such traumatic bleeding is seldom voluminous or rapid. However, in contrast with even the severe hemophiliac, slow persistent oozing may follow trivial cuts, eg, razor nicks, scratches. Delayed bleeding and spontaneous hemarthrosis, characteristic of the hereditary coagulation disorders, are extremely rare in ITP.

### Clinical Course

The clinical course of ITP is quite variable, but the differences between acute and chronic cases are striking (Table 34-4). In *acute ITP*, the disorder usually is self-limited and *spontaneous remissions* occur in as many as 93% of the patients.<sup>75</sup> The duration of the disease ranges from a few days to a few months and averages four to six weeks.<sup>84,89</sup> The favorable prognosis of ITP in children (Fig. 34-4) reflects the preponderance of the acute form in this age group. In patients with *chronic ITP*, a fluctuating clinical course usually is noted. Episodes of bleeding may last a few days or a few weeks, and may be *intermittent*<sup>4</sup> or even *cyclical*.<sup>338</sup> Cessation of

Fig. 34-4 Age and sex distribution of 55 cases of idiopathic thrombocytopenic purpura

bleeding may be associated with a rapid increase in the number of platelets, even to values above normal, but more often thrombocytopenia of variable degree persists. Spontaneous remissions are uncommon and are likely to be incomplete.<sup>53</sup> Relapses in some cases appeared to be associated with vaccinations and exposure to insecticides.<sup>209</sup> Not infrequently, the clinical course is surprisingly benign. In one patient, who refused splenectomy, chronic ITP with platelet counts averaging  $50 \times 10^9/l$  has persisted for 40 years without serious complications or treatment.<sup>130</sup>

## Laboratory Findings

### The Blood

The platelets may be totally absent or only slightly decreased in number. Bleeding is uncommon if the platelets number in excess of  $50 \times 10^9/l$ , but the platelet count often correlates poorly with the severity of the hemorrhagic manifestations, particularly in chronic cases.

Abnormalities in *platelet size and morphologic appearance* are common. The platelets often are abnormally large, eg, 3 to 4  $\mu m$  in diameter, and reveal more than normal variation in size and shape. These changes are attributable to accelerated thrombopoiesis, and are most apparent in chronic cases. The presence of such "megathrombocytes" provides indirect evidence of accelerated platelet production, and correlates roughly with the

number of megakaryocytes in the marrow.<sup>245</sup> Large platelets are commonly present for months following successful splenectomy.<sup>61</sup> More striking morphologic changes may be seen in some subjects, eg, "giant" forms 10  $\mu m$  or more in diameter, minute platelets, bizarre shapes, and deeply stained forms. Sometimes, megakaryocyte fragments may be noted in the blood smear.

Qualitative abnormalities of platelet function also have been described in ITP,<sup>11</sup> and have been attributed to coating of the platelets with antibody.<sup>20</sup> There is little evidence that these abnormalities are of significance in the production of bleeding, and some of the reported results may merely reflect the predominantly young platelet population that is usually present in this disorder.

Anemia, if present, is proportional to the extent of blood loss and is usually normocytic. If bleeding has been severe and long continued, iron-deficiency anemia develops. Occasionally, if there has been a recent severe hemorrhage, there may be reticulocytosis and moderate macrocytosis.

The *total leukocyte count* and the *differential count* usually are normal, except for those changes resulting from acute bleeding, eg, slight to moderate neutrophilia with some increase in immature forms. In some patients,<sup>23,66</sup> particularly children, eosinophilia has been noted, but this is by no means a consistent finding. Lymphocytosis with abnormal cells resembling those found in infectious mononucleosis also has been reported.<sup>85,103,128</sup>

Tests of *hemostasis and blood coagulation* reveal only those changes attributable to thrombocytopenia, ie, a prolonged bleeding time, absent or deficient clot retraction, positive reaction to the tourniquet test, and deficient prothrombin consumption. Since platelet enumeration is now far more accurate than any of these confirmatory tests, the tests are not indicated merely to confirm the presence of thrombocytopenia, as they once were. The results of tests of blood coagulation, eg, prothrombin time, partial thromboplastin time, coagulation time, are normal in patients with uncomplicated thrombocytopenia.

## The Marrow

Alterations in the bone marrow in ITP are limited to the megakaryocytes except for the normoblastic hyperplasia that may develop as the result of blood loss. The leukocytes are essentially normal. Eosinophilia has been described in many patients with acute ITP,<sup>75</sup> but the assertion that this finding is an index of good prognosis has not been confirmed.<sup>30,37</sup>

The megakaryocytes (Plate XIV) are plentiful in number,<sup>28,394</sup> and usually are increased in size.<sup>395</sup> "Young" forms with single nuclei, scanty cytoplasm, and relatively few granules are commonly seen. Morphologic abnormalities of these giant cells are present in most patients with ITP.<sup>39,91,459</sup> Vacuoles of various sizes may be present in the cytoplasm, particularly in the periphery; degenerating forms are not uncommon.<sup>459</sup> Unusually small and exceptionally large megakaryocytes with non-lobulated nuclei, many vacuoles, and few granules in the cytoplasm also have been described.

Examination of the bone marrow is helpful mainly in ruling out the possibility of other conditions with which ITP may be confused. The changes summarized above are similar to those found in most forms of thrombocytopenia caused by accelerated platelet destruction (Table 34-3),<sup>258</sup> and are not characteristic or diagnostic of ITP. The differences between megakaryocytes found in the acute and chronic forms of ITP are not clearcut,<sup>65,73</sup> and marrow examination is not particularly helpful in determining prognosis. Differential counting of the megakaryocytes has proved useful in some hands,<sup>65,459</sup> but is not widely used.

## Miscellaneous

The plasma  $\beta$ -glycerol acid phosphatase level may be elevated in any form of thrombocytopenia caused by accelerated platelet destruction.<sup>443</sup> The utility of this method in differentiating between thrombocytopenia caused by accelerated platelet destruction and that resulting from deficient production has

been questioned,<sup>358</sup> and the technique has not been widely accepted as a diagnostic adjunct in ITP.

Measurements of platelet survival and sequestration are of uncertain diagnostic or prognostic value. Like the aforementioned serologic tests, these techniques are important tools for elucidating the pathophysiology of the syndrome, but with extant methods the information obtained is of limited clinical value.

## Differential Diagnosis

Like anemia, *thrombocytopenia is a symptom*, and the diagnosis of ITP requires that the numerous disorders that may produce secondary thrombocytopenia be excluded (Table 34-2). The importance of careful inquiry regarding *drug ingestion* or exposure to *toxic substances* cannot be overemphasized, since thrombocytopenia due to drugs or toxins often is indistinguishable from ITP. The development of thrombocytopenia in an adult, in particular, should arouse suspicion of a chemical etiologic agent, since many of the drugs associated with thrombocytopenia (Table 34-5) are used more frequently by adults than by children.

Some forms of *hereditary thrombocytopenia* (page 1100) are indistinguishable from ITP on clinical grounds. This is particularly true of the autosomal dominant forms. Furthermore, a misleading family history in the absence of objective evidence of thrombocytopenia is not uncommon in ITP.<sup>51,100,121,137</sup> A discriminating family history, careful laboratory study of platelet function, and, if necessary, examination of other family members may be required to exclude the possibility of hereditary thrombocytopenia.

*Splenomegaly*, even when present,<sup>344,371</sup> is never great. Massive splenomegaly suggests an underlying disease. Lymphadenopathy, icterus, and hepatomegaly also point to a secondary form of thrombocytopenia.

An *underlying hematologic disorder* is suggested by anemia out of proportion to blood loss, and by changes in the leukocytes not attributable to hemorrhage or complicating

infection. Persistent leukopenia suggests leukemia, aplastic anemia, a disorder of the spleen, or *disseminated lupus erythematosus*.<sup>379</sup> In the last-named disorder, thrombocytopenia may be noted months or even years before other manifestations of the disease appear,<sup>371</sup> and the possibility of this condition should always be excluded by tests for nuclear-binding antibodies, and by LE preparations. Serum protein electrophoresis also is valuable, since hyperglobulinemia is common in SLE and in other disorders associated with secondary thrombocytopenia. Serum proteins and the complement level<sup>115</sup> are normal in ITP. Increased plasma levels of fibrinogen degradation products, schistocytes in the blood smear, or coagulation abnormalities suggest *diffuse intravascular coagulation* (Chapter 38) or a *microangiopathic process* (Chapter 28). Occult carcinoma, sarcoidosis, and various lymphomas may occasionally mimic ITP.

*Bone marrow aspiration* is particularly valuable in the differential diagnosis of ITP because of the large number of disorders associated with thrombocytopenia in which characteristic changes are present in the bone marrow. The initial manifestations of acute leukemia, multiple myeloma and other paraproteinemias, myelophthisic processes, and aplastic anemia may mimic ITP. Although, as emphasized above, the changes in the marrow in ITP are not diagnostic of this disorder, the absence of megakaryocytes in a normally cellular bone marrow aspirate suggests a secondary form of thrombocytopenia.

### Treatment

The course of ITP is so varied that it has been difficult to evaluate therapeutic measures. If one overlooks the possibility of spontaneous remissions, if differences in patient population, particularly age are ignored, and if one makes observations on a small number of cases for a short enough period of time, it becomes possible to make a case for many therapeutic procedures, as a review of the earlier literature concerning this syndrome

makes abundantly clear. From time to time, a large variety of remedies have found their advocates, only to be forgotten. These include, to name but a few, foreign protein injections,<sup>42</sup> turpentine, snake venoms,<sup>92,106</sup> ultraviolet light,<sup>251</sup> heliotherapy, vitamin P,<sup>70</sup> ascorbic acid,<sup>88</sup> toluidin blue, and roentgen irradiation of the spleen.<sup>82</sup> The coumarin anticoagulants and heparin were claimed to have produced beneficial effects in some cases; the rationale of such therapy is obscure. The infusion of very large doses of fresh normal plasma appeared to induce remissions in some children with acute ITP, but were ineffective in patients with chronic ITP.<sup>8,72,90</sup> The therapeutic role of all of these procedures remains uncertain. On the other hand, splenectomy and adrenal corticosteroids have withstood the test of time, and are the mainstay in the treatment of ITP. Immunosuppressive agents may be effective in patients who are refractory to these modes of therapy (page 1087).

### Conservative Management

The acute form of ITP observed in children has an excellent prognosis. As many as 93%<sup>73</sup> of affected children will make a complete recovery without any therapy. Recovery without therapy occurred within three months of onset in 75% of children with ITP and in most this occurred within four to six weeks.<sup>89,113</sup> The mortality rate is extremely low.<sup>73</sup> As a consequence, in children with mild bleeding manifestations, particularly if the disorder has developed soon after an acute infection,<sup>16,75</sup> only careful observation is indicated. Spontaneous recovery in older patients is less consistent or common, but many experienced hematologists manage mild cases in adults expectantly.

Conservative therapy is inadvisable if bleeding is severe, or if careful followup cannot be assured. It is somewhat more hazardous and unpredictable in females from puberty until the menopause, since excessive menstrual bleeding carries a risk not shared by males. The estimate of "severity" is ad-

## PLATE XIV

*Normal megakaryocyte and megakaryocytes from patients with idiopathic thrombocytopenic purpura (X1200)*

1. Mature megakaryocyte. Note granularity of cytoplasm, pseudopods, and the presence of platelets, which are situated chiefly at the periphery of the cell and in the pseudopods.

2. Megakaryoblast.

3. Mature megakaryocyte or intermediate form from a patient with chronic idiopathic thrombocytopenic purpura. There is well-defined granularity of the cytoplasm, but no platelet formation.

4. Mature megakaryocyte from a patient with chronic idiopathic thrombocytopenic purpura. There is almost complete lack of granularity and marked vacuolization and degeneration of the cytoplasm.

5. Intermediate form of megakaryocyte from a patient with acute idiopathic thrombocytopenic purpura. Granule formation, without platelet development, is evident and there are some questionable nuclear bodies (asynchronism of development) in the cytoplasm.

6, 7. Lymphoid megakaryocytes from a patient with acute idiopathic thrombocytopenic purpura. These are characterized by blue cytoplasm, lack of granularity, and lack of platelet formation.

8. Promegakaryocyte from patient with acute idiopathic thrombocytopenic purpura 24 hours after splenectomy. Nongranular platelet formation is present around the periphery of the cell, with a streamer containing a group of newly formed platelets.

9, 10. Intermediate form and mature megakaryocyte from a patient with acute idiopathic thrombocytopenic purpura 48 hours after splenectomy. There is a striking productivity of granular (functioning) platelets, seemingly with the entire cytoplasm almost ready to break up into platelets. (From Dameshek and Miller, courtesy of the authors and Grune & Stratton, Inc.)

mittedly difficult to make, and in an occasional patient the course of this disorder may become unexpectedly fulminant. However, serious hemorrhage is rare if the platelet count is  $50 \times 10^9/l$  or higher, or in patients in whom the duration of the disorder has been greater than two months.<sup>16</sup> Except for patients with very mild ITP in whom no therapy is required, expectant therapy should be limited to a period of not more than six months, since spontaneous remissions are exceedingly rare beyond this time.

### Corticosteroids

Some increase in platelet numbers and a favorable clinical response ("*partial*" remission) can be expected in 70 to 90% of patients with chronic ITP who are treated with adrenal corticosteroids. The number of patients in whom these hormones alone produce a complete normalization of the platelet count ("*complete*" remission) is much smaller, and ranges from 15 to 60%<sup>29,130,371</sup>; complete remissions of sustained duration are even less common.<sup>16,84</sup> A favorable response is usually seen in a matter of days, although, in an occasional patient, one to two months of therapy are required. The efficacy of steroid treatment is difficult to evaluate in the acute form of the disorder in children.<sup>18,75,131</sup>

**MECHANISM OF ACTION.** Corticosteroids do not increase platelet production,<sup>115,116</sup> and there is no evidence that they impair the interaction between antibodies and platelets, or that they significantly impair immunoglobulin synthesis<sup>7</sup> except perhaps after protracted administration.<sup>134</sup> Contrary to a widely held assumption, there is no direct evidence that corticosteroids reduce capillary fragility.<sup>11,101,122</sup> There is some evidence that these hormones diminish platelet sequestration in the spleen as the result of a general impairment of reticuloendothelial clearance functions.<sup>113,116,438</sup>

**INDICATIONS; REGIMENS.** Views differ regarding the exact indications for corticosteroid therapy in ITP. Although splenectomy remains the most effective measure in terms

of ultimate cure, corticosteroids are widely used as the initial therapeutic modality. It is the authors' practice to initiate corticosteroid therapy in most patients with ITP who are not selected for conservative management.

There is no evidence that any particular form of adrenal corticosteroid has any advantage over prednisone.<sup>11</sup> Various regimens have been recommended. One commonly used in initiating therapy is that of giving 40 to 60 mg of prednisone daily to adults, and 1 mg/kg body weight to children. Only in an occasional patient will larger doses produce a better response. The initial course of steroids should be maintained for three to four weeks followed by a gradual tapering of the dosage and then discontinuing the use of the drug.

If a complete remission was initially induced with steroids, but relapse occurred when their use was discontinued, there is some evidence that a second course may still produce a complete remission.<sup>130</sup> However, if the initial course of steroids produced no response, it is very unlikely that subsequent courses will be effective. When a partial remission is obtained, splenectomy, a period of expectant therapy, or maintenance at a lower dose may be indicated as dictated by individual factors.

Steroid therapy should not be maintained for long periods, a reasonable rule of thumb being six months. Although the use of modest doses of these drugs for a short time carries little risk, the often devastating effects of long-term corticosteroid therapy need little emphasis (page 555).

In patients with severe ITP who have not responded to steroids in the usual doses, it is common practice to increase the dosage to high levels (80 to 100 mg of prednisone, or even more, daily) for a brief period prior to splenectomy. In some patients, this produces some increase in platelet numbers and this may minimize surgical bleeding or serious bleeding complications. Such high doses can usually be given for three to seven days with safety<sup>134</sup>; the dosage should then be promptly tapered. The long-continued administration

of high doses (100 mg of prednisone or more) may suppress platelet formation and lead to therapeutic failure or relapse following an initial remission.<sup>24</sup> The mechanism of this effect is obscure.

### Splenectomy

The value of splenectomy in the treatment of patients with ITP has long been recognized. This procedure was first performed in 1916, at the suggestion of Kaznelson, who, at the time, was still a medical student<sup>57,63</sup>; it remains the ultimate therapeutic measure of choice in the majority of patients. Following the operation, the platelet count may increase rapidly, often within 28 to 48 hours,<sup>371</sup> and may reach levels as high as  $1000 \times 10^9/l$  or even higher in about 10 days. Not infrequently it rises more slowly. Normalization of the bleeding time and a reduction in capillary fragility may be noted before the platelet count increases.<sup>101</sup>

Complete and sustained remissions have followed splenectomy in from 50 to 88% of the patients.<sup>9 16,37 91 135</sup> In many of the remaining patients, some increase in platelet numbers and amelioration of bleeding manifestations have been observed.

**RATIONALE.** The effectiveness of splenectomy in ITP presumably is the result of the removal of the organ that is mainly responsible for the sequestration of antibody-sensitized platelets. Even when this procedure eventuates in a complete remission, evidence of increased platelet production and decreased platelet survival may persist.<sup>45 285</sup> In such cases, splenectomy appears to convert a "decompensated" state of platelet destruction into a "compensated" one, in which platelet production can keep up with continuing destruction. Evidence concerning antibody production by the spleen was discussed above. The removal of this organ may result in a reduction of antibody levels,<sup>61</sup> but this is of little apparent significance in the immediately favorable effects of splenectomy.

**INDICATIONS; CONTRAINDICATIONS.** The *indications* for splenectomy in patients with

ITP might be briefly stated as follows: (1) failure of spontaneous remission to occur after six or more months of observation in patients whose clinical manifestations are moderate or severe; (2) failure to respond to steroid therapy, occurrence of relapse following discontinuance of the use of or reduction in the dosage of steroids, and the requirement of high doses for maintenance of a clinical status free of serious hemorrhage; (3) when adequate follow-up cannot be assured, when overriding contraindications to the use of steroids are present, and, rarely, when growth, development, or social or economic status is uniquely impaired by the effects of steroid therapy or by recurrences of bleeding.

There are numerous differences of opinion regarding the exact indications for splenectomy, and, in the last analysis, the ultimate decision must be individualized.

Splenectomy is *contraindicated* in ITP: (1) early in the first episode of bleeding, especially in children, because of the frequency of spontaneous remissions; (2) in patients with acute, fulminating cases in whom the mortality following splenectomy has been high; (3) in patients with cardiac or other complications that contraindicate any major surgical procedure; (4) in children under two years of age, in whom the hazard of fulminating infection following splenectomy is greater than at a later age (page 360); and (5) in most cases of ITP in pregnant women (page 1088). Some physicians have considered acute fulminating hemorrhage to be an indication for splenectomy,<sup>46</sup> however. In such circumstances they have given platelet transfusions and steroids as well.

Other objections to splenectomy that have been raised are not well founded. It is probable that surgical morbidity and mortality due to bleeding in patients with thrombocytopenia, emphasized in the older literature, have been exaggerated. Less than 1% mortality has been the general experience in recent years.<sup>17,91,371</sup> Even patients with platelet counts as low as  $5 \times 10^9/l$  have tolerated splenectomy without undue bleeding.<sup>333</sup> The possibility that splenectomy "unmasks" or

causes an exacerbation of systemic lupus erythematosus has been cited by some,<sup>29,453</sup> but evidence for this phenomenon is almost totally lacking.<sup>84,112,339</sup> The response to the LE test may, however, become positive for the first time after operation.<sup>455</sup>

**SPLENECTOMY FAILURE.** In from 5 to 20% of patients with ITP, splenectomy produces little or no lasting benefit. Unfortunately there is no way of predicting this prior to the operation. The value of *measurements of in vivo platelet sequestration* is controversial. Of 74 patients with "predominantly" splenic sequestration in one large series, 73% enjoyed a good response following splenectomy, whereas among 19 patients with predominantly hepatic sequestration, such a response was noted in only three.<sup>87,121</sup> Others have reported less consistent results.<sup>3,4,475</sup> Measurements of the "sequestration pattern" are fraught with several methodologic difficulties,<sup>3,475</sup> and may fluctuate significantly from time to time.<sup>3</sup> "Hepatic" sequestration patterns have been documented in several patients who responded well to splenectomy.<sup>3,4,87,120</sup>

Other clinical and laboratory features of the disorder were predictive of a poor result following splenectomy in some groups of patients but not in others; eg, a high level of platelet antibodies or of "ITP factor" as measured *in vivo*, or the absence of platelet-agglutinins<sup>47</sup>; a poor response to corticosteroids<sup>130</sup>; an enlarged spleen; the absence of brisk thrombocytosis seven days following the operation.<sup>91</sup> It is probable that all of these criteria have some prognostic value, but, in practical terms, none is sufficiently reliable to exclude the likelihood of a potentially favorable response to splenectomy.<sup>3,4,58</sup> The duration of the disease prior to splenectomy<sup>344</sup> appears to be of no prognostic significance.<sup>29,55,130</sup>

Accessory spleens are mentioned frequently as a cause of failure of splenectomy. These aberrant organs are most commonly located in the splenic pedicle, the pancreas, and the peritoneum in the immediate neighborhood of the spleen, but in rare instances they have

been found in the pelvis—near the ovaries in women and in the scrotum in males.<sup>35</sup>

Radiologic techniques involving the injection of Thorotrast or red cells labeled with <sup>51</sup>Cr-chromate or mercury have been of dubious value in localization of accessory spleens.<sup>73,407</sup> This problem may be solved by newer, more sensitive scanning techniques, eg, those using <sup>99m</sup>Tc.<sup>22,32</sup>

In a few patients, surgical exploration has revealed accessory spleens and their removal has brought about remissions.<sup>35</sup> Opinions concerning the likelihood of such a successful result of exploration differ widely.<sup>16,27,421</sup> Surgeons have learned to look for accessory spleens at the time of the original operation and also to take care that implantation splenosis does not occur as the result of rupture of the spleen. In most patients with ITP in whom splenectomy fails to effect a "cure," other explanations must be sought.

The mainstay in the treatment of patients who have failed to respond to splenectomy is corticosteroids. In such patients, 40 to 60 mg of prednisone are administered until the platelet count reaches a maximum. The dose is then progressively tapered to the minimum required to control bleeding effectively. The severity of hemorrhagic manifestations, rather than the platelet count, should be the major criterion. Careful follow-up and frequent changes of dosage may be required, and sound clinical judgment regarding the occupational, financial, and psychologic effects of both bleeding and hypercorticism is essential. Some patients, observed for years with platelet count of 10 or even  $5 \times 10^9/l$  have had no significant bleeding other than some ecchymoses or petechiae, even with no steroid therapy.

Preliminary results with immunosuppressive drugs have been encouraging in some cases of ITP, but not in others.<sup>8</sup> Azathioprine,<sup>12,54,127</sup> cyclophosphamide,<sup>68</sup> actinomycin,<sup>76</sup> and other agents,<sup>12</sup> either given alone or in combination with corticosteroids,<sup>12</sup> have produced sustained remissions in some subjects. This mode of therapy has yet to be thoroughly evaluated, but the reported results are nevertheless noteworthy since they were ob-

tained in patients who had failed to respond to splenectomy or corticosteroids. Immunosuppressive therapy should probably be reserved for such refractory cases.<sup>36</sup>

### Supportive Measures

Physical activity should be restricted so as to minimize the hazards of trauma. Blood loss should be treated as otherwise indicated (page 698). Fresh blood provides more viable platelets than stored blood, but transfusion of 1 to 2 units, as may be required for the repletion of red cell mass, does not provide significant numbers of platelets. If it is desired to administer platelets, concentrates should be employed<sup>333</sup> (Chapter 12). However, such *platelet transfusions* are less effective in this disorder than in secondary forms of thrombocytopenia.<sup>507</sup> Even large numbers of platelets produce only a slight and transient increase in the platelet count, no doubt because of the rapidity with which they are sequestered *in vivo*.<sup>333, 507</sup> Platelet transfusions nevertheless may diminish bleeding for a time, and in some patients appeared to be effective in the management of serious complications, eg, subarachnoid hemorrhage. They should be reserved for such life-threatening emergencies, or for the immediate preoperative treatment of patients with serious hemorrhage prior to splenectomy.<sup>333</sup> In most patients with platelet counts above  $50 \times 10^9/l$ , preoperative platelet transfusions are not indicated.<sup>333</sup> Platelet replacement should be avoided in patients with chronic ITP because this may lead to the development of isoantibodies (Chapter 12). Anovulatory medications have proved useful when menorrhagia is a major complaint.

### Clinical Variants of ITP

Several variants of ITP have unique features worthy of mention. *Onyala* is a disorder of unknown cause observed in Africa.<sup>71, 124</sup> Hemorrhagic bullae inside the mouth and on other mucous surfaces are particularly common. With the exception of this manifestation, a possibly shorter course, and a tendency to affect young adult males as well as

children, this form of acute thrombocytopenia in the Bantu does not differ from ITP.<sup>494, 83</sup>

Several cases of ITP have been associated with the presence of *lipid-laden macrophages* in the spleen. Inclusions of at least two different types have been described, ie, those composed mainly of cholesterol<sup>64</sup> and those containing a ceroid-like substance.<sup>109</sup> This finding was first noted in patients with ITP who did not respond favorably to splenectomy<sup>31</sup> and is most common in those who have received large amounts of corticosteroids.<sup>18, 64, 110</sup> It has been suggested that the lipids may be deposited as the result of the metabolic effects of corticosteroids,<sup>64</sup> or are derived from the breakdown of sequestered platelets within macrophages.<sup>37</sup> This finding is much more common than previously suspected, and the disorder does not otherwise differ from the usual case of ITP.

### ITP in Pregnancy

The syndrome of ITP in pregnancy differs from that discussed above in four respects; namely, (1) there is a twofold increase in the incidence of spontaneous abortion<sup>102</sup>; (2) there is an increased incidence of intrapartum and postpartum bleeding as the result of thrombocytopenia; (3) thrombocytopenia and perinatal hemorrhage occur in the majority of infants borne of such mothers; and (4) corticosteroids and splenectomy may be hazardous to both mother and child.<sup>52, 377</sup>

The overall maternal mortality in pregnancy complicated by ITP is very low.<sup>81, 108</sup> However, mortality in untreated patients in whom ITP antedated pregnancy was reported to range from 7 to 11%.<sup>33, 102, 129</sup> A particularly bad prognosis has been reported in women in whom splenectomy was performed during pregnancy.<sup>129</sup> When thrombocytopenia was still present at the time of delivery, postpartum hemorrhage was slightly more common than in uncomplicated pregnancy,<sup>53</sup> and appeared to originate mainly from operative incisions and lacerations rather than from the uterus.<sup>103, 123</sup>

*Therapy* of the pregnant patient with ITP must be individualized; neither of the major

therapeutic measures is without risk. Although it has been stated that corticosteroids may induce congenital anomalies if employed in the first trimester,<sup>46</sup> this hazard appears to have been greatly exaggerated.<sup>53</sup> The therapeutic response to steroids in pregnant patients is quite similar to that which would be expected in nonpregnant patients, although there is some evidence of an increased incidence of eclampsia and postpartum psychosis.<sup>53</sup> Available data would suggest that the hazards of splenectomy exceed those of corticosteroids, and these hormones, in the doses described above, possibly supplemented with platelet transfusions at term in the severely affected patient, are preferable to splenectomy in the treatment of ITP in the pregnant patient.

Splenectomy, in common with any major surgical procedure early in pregnancy, is a well-recognized cause of abortion.<sup>102</sup> In one series, fetal mortality as high as 25% was reported,<sup>129</sup> but, in the experience of others, the incidence of fetal death was approximately the same whether splenectomy or conservative measures were employed.<sup>81, 108</sup> It is probable that the truth lies somewhere between these views, and that splenectomy constitutes a significant although not prohibitive hazard to the fetus regardless of the stage of gestation and should be avoided if at all possible.

ITP in the infant is discussed below, together with other forms of congenital immunologic thrombocytopenia.

### Pathology

The findings in the bone marrow have been described (page 1083). The spleen usually is normal in size<sup>371</sup> but may be slightly enlarged.<sup>138</sup> The average weight in one series of adult patients was 227 g.<sup>90</sup> The increase in the size of the spleen is thought to be due to congestion of the sinusoids and an increase in the size of the germinal centers of the lymphoid follicles.<sup>13, 50, 341</sup> Eosinophilic and neutrophilic leukocytes and megakaryocytes are found in the splenic sinuses.<sup>60</sup>

Histologic study of the purpuric lesions has been made.<sup>92</sup> In fatal cases of ITP, extensive hemorrhages are noted both grossly

and microscopically. Subarachnoid hemorrhage and petechial hemorrhages in virtually the entire brain ("brain purpura") are often in evidence. The spinal cord also may be involved. Subdural hemorrhage, pachymeningitis, and even hemorrhagic encephalitis also have been described.

### Other Forms of Immunologic Platelet Destruction

#### Congenital Immunologic Thrombocytopenia

Congenital immunologic thrombocytopenia in the newborn may result from the placental transfer of platelet antibodies. Such antibodies may arise from the active immunization of the mother by fetal platelet isoantigens (*isoimmune type*) (Fig. 34-5) or from the passive transfer of autoantibodies present in the maternal circulation as the result of ITP ("congenital" ITP).

### Pathophysiology

Pathophysiologically, the *isoimmune type* is similar to erythroblastosis fetalis (Chapter 27). Thus, as a consequence of the inheritance by the fetus of platelet isoantigens lacking in the mother, isoantibodies are formed in the maternal circulation; these isoantibodies cross the placenta and produce thrombocytopenia in the fetus.<sup>448</sup> Immunization to four such isoantigens has been documented, ie,  $PI^{A1}$  (ZW<sup>a</sup>),  $PL^{E2}$ ,  $PIGrLy^{B1}$ , and  $PIGrLy^{C1 475}$  (Chapter 12). Although thrombocytopenia and bleeding are infrequent, isoimmunization to platelet antigens is not uncommon; it often occurs during the first pregnancy.

Of viable infants borne of mothers with ITP, 35 to 70% will have thrombocytopenic purpura.<sup>441, 53</sup> This is due to the passive placental transfer of the "ITP factor." Such congenital ITP may develop in infants borne of mothers who are in remission following splenectomy,<sup>41, 52, 53</sup> but is uncommon when the mother has undergone a spontaneous or a steroid-induced remission.

Rarely, thrombocytopenia in the neonate results from the passive transfer of maternal

autoantibodies induced by drugs, such as quinine<sup>296,218</sup> (page 1091), and those associated with SLE.<sup>437</sup>

### Clinical Features

Irrespective of the etiologic basis, the clinical features of congenital immunologic thrombocytopenia are similar. Bleeding is seldom life-threatening, and the disorder is frequently very mild or even subclinical. Generalized petechiae and ecchymoses often are prominent, and in infants with the congenital type of ITP they are usually present at birth. In infants with thrombocytopenia of the isoimmune type, purpura often is first seen when they are one to two weeks of age. Icterus, due to indirect bilirubin absorbed from blood in the skin, is commonly present in infants with either type of the disorder.

In a minority of infants with congenital ITP, hemorrhage may be severe and the course during the perinatal period may be stormy. The first few days of life appear to be particularly critical, intracranial hemorrhage is the most common cause of death. The majority of such severely affected infants were the offspring of mothers who were thrombocytopenic at the time of delivery.<sup>41,430</sup>

### Laboratory Diagnosis

Thrombocytopenia usually is marked. In most infants with congenital ITP, the bone marrow reveals normal or increased numbers of megakaryocytes. In some cases due to isoimmunization, marked hypoplasia of the megakaryocytes has been noted and has been attributed to damage to the precursor by the antibody.<sup>475,479</sup>

Serologic tests, employing techniques such as complement fixation, which will be discussed below, will detect the presence of an antibody in approximately 70% of infants with ITP due to isoimmunization. These techniques, however, are available only in specialized laboratories. In the remaining patients the antibodies are "incomplete," and can be demonstrated only by their blocking action against isoantibodies of known speci-

ficity, or by their *in vivo* effects in normal subjects.<sup>479</sup> The serologic detection of autoantibodies in congenital ITP was discussed on page 1077.

### Differential Diagnosis

In the differential diagnosis of congenital immunologic thrombocytopenia the many and varied causes of *thrombocytopenia in the newborn* must be considered. Those unique to the neonate include various congenital infections (particularly syphilis<sup>283,321</sup>), toxoplasmosis,<sup>375</sup> cytomegalic inclusion disease,<sup>329</sup> rubella, and disseminated herpes.<sup>442</sup> Intravascular coagulation is a serious problem in the neonate<sup>442</sup>; it most commonly results from septicemia. Rarely, DIC may be "transferred" passively from the maternal circulation (page 1213). Drugs ingested by the mother, such as chlorothiazides, and congenital thyrotoxicosis<sup>503</sup> are rare causes of neonatal thrombocytopenia. Infiltration of the marrow presumably is the cause of neonatal thrombocytopenia in congenital forms of leukemia<sup>442</sup> and in the reticuloendothelioses.<sup>409</sup> Other sections in this chapter are devoted to a discussion of the hereditary thrombocytopenias (page 1100) and congenital megakaryocytic hypoplasia (page 1096).

As discussed in Chapter 9, the platelet counts in thriving *prematures* approximate those in normal neonates and adults.<sup>325,383</sup> "Physiologic" thrombocytopenia, in many cases, may well be the result of an unrecognized infection or toxin in a particular nursery.<sup>442</sup> Thus, thrombocytopenia in the premature, as in other infants or adults, requires a careful search for an etiologic factor.<sup>447</sup>

Thrombocytopenia is commonly associated with severe *erythroblastosis fetalis* (Chapter 27) but appears to be unrelated to platelet antibodies. The pathophysiology of thrombocytopenia in this disorder is complex and poorly understood. Numerous factors may be of pathophysiologic importance, including the effects of the products of red cell breakdown, bilirubin,<sup>374,489</sup> antigen-antibody complexes (page 1101), exchange transfusions,<sup>368</sup> and intravascular coagulation.<sup>352</sup>

## Treatment

In the majority of infants, no therapy is required since bleeding usually is *minimal*. However, the overall mortality due to bleeding in infants with congenital ITP ranges from nil to 25%<sup>53,102,129,330</sup>, in those with *isoimmune thrombocytopenia*, a 13% mortality rate has been reported.<sup>475</sup> The platelet count returns to normal as the responsible antibody disappears from the circulation. This usually occurs within one to four weeks, but rarely as many as four months may be required.<sup>442</sup> Recovery following *isoimmune thrombocytopenia* usually is more rapid than that following congenital ITP.<sup>479</sup>

Even though infused platelets are destroyed rapidly, platelet transfusions may be particularly effective in the infant because of the small blood volume. If immunologically reactive platelets must be administered to infants with ITP due to isosensitization, the transfusion should be given slowly. Platelets of assured compatibility can be prepared by plasmapheresis of the mother.<sup>327</sup> The therapeutic efficacy of corticosteroids and exchange transfusion<sup>53,346,405,479</sup> in these disorders remains uncertain because of insufficient data. Exchange transfusion has been recommended for infants with *isoimmune thrombocytopenia* in whom severe thrombocytopenia, jaundice, or megakaryocytic hypoplasia is present.<sup>475</sup>

### Post-transfusion Thrombocytopenia Due to Isoantibodies

The isoantibodies resulting from the transfusion of incompatible platelets are discussed in Chapter 12. The usual effect of such isoantibodies is the destruction of only the infused incompatible platelets. Rarely, however, severe thrombocytopenia is produced by the transfusion of incompatible platelets.

A unique immunologic mechanism apparently underlies platelet destruction in this condition. In all documented cases, the platelets of affected patients were negative for platelet antigen  $PI^{A1}$  ( $ZW^a$ ),<sup>475</sup> but the responsible antibody was specific for  $PI^{A1}$ .

positive platelets. A history of prior transfusion has rarely been obtained, but the disorder has been observed only in women with a history of one or more pregnancies.<sup>475,478</sup> The mechanism by which an isoantibody destroys autologous  $PI^{A1}$ -negative platelets has yet to be explained. Cross reaction with an unidentified second antibody<sup>430</sup> or antigen-antibody complexes may possibly explain the thrombocytopenia.<sup>475,478</sup>

Thrombocytopenia usually is persistent and bleeding may be severe. In one patient, the platelet count remained subnormal for two months following a single blood transfusion.<sup>430</sup> Exchange transfusion was immediately and permanently effective in two patients,<sup>354,478</sup> but no other mode of treatment is of established value. In contrast to other forms of immunologic thrombocytopenia, severe febrile reactions have followed platelet transfusions in several patients with this disorder.<sup>478</sup>

### Thrombocytopenia Due to Drug-Induced Antibodies

Thrombocytopenia due to drugs and chemical agents has become increasingly common during the past two decades. Indeed, in this age of drugs and chemicals the presence of potentially toxic agents in the environment has now become so widespread that it is seldom possible to truly exclude exogenous toxins as a cause of thrombocytopenia. It is not improbable that many cases of "idiopathic" thrombocytopenia, as well as relapses from ITP previously in remission, may be the result of occult environmental toxins.<sup>210</sup>

The numerous chemical and physical agents that may be associated with thrombocytopenia are summarized in Table 34-5. With the exception of those that suppress platelet production (group I-B) and are discussed below, it must be recognized that only a few drugs have been related to the production of thrombocytopenia beyond the statistical probability of coincidence, eg, quinine, quinidione, fudarin, Sedormid, digitoxin. In most cases, the evidence relating a given drug to the production of the dyscrasia is only

Table 34-5. Chemical Agents Which May Produce Thrombocytopenia\*

## I AGENTS THAT SUPPRESS PLATELET PRODUCTION

A Those that produce generalized bone marrow suppression (Table 56-2, page 1746)

B Those that selectively suppress the megakaryocyte

Chlorothiazides<sup>181, 411</sup>Estrogenic hormones<sup>184, 256</sup>Ethanol<sup>212, 213, 212</sup>Tolbutamide<sup>239</sup>

\*Within groups agents are listed alphabetically

†The majority probably act by means of an immunologic mechanism, but definite evidence for antibodies is lacking

‡Agents not documented by specific case reports are cited in references 96, 143, 146, 165, 188, 196, and 201

Fig 34-5 Reactions involved in immunologic platelet injury A. Isoantibodies B. Drug induced platelet autoantibodies (the innocent bystander hypothesis) Key c = carrier molecule, h = hapten (drug), pi = platelet, a = antibody

circumstantial. In the case of drugs that are taken by a significant percentage of the population, the association between the drug and the dyscrasia may be merely coincidental, eg, aspirin.

Convincing evidence for the presence of drug-induced platelet antibodies, such as positive reactions to *in vitro* serologic tests or the production of thrombocytopenia by readministration of the drug to sensitive individuals, has been documented only for those drugs listed in group II. There is indirect evidence that the drugs listed in group III-B also act by means of an immunologic mechanism. Several reviews of drug-induced thrombocytopenia may be consulted for further details.<sup>143, 146, 165, 183, 196, 201</sup>

### Pathophysiology

Drug-induced platelet antibodies are the result of an idiosyncratic reaction, which develops in only a very small proportion of persons exposed to a drug. This ranges from approximately 1 in 100,000 persons for quinidine to as many as 1 in 100 for gold salts.<sup>192</sup> The determinants of such idiosyncrasy remain obscure.

In some cases of thrombocytopenia due to hydrochlorothiazide<sup>172</sup> and in one associated with rifampin<sup>157</sup> an IgM antibody was documented. In all other cases, the responsible antibodies have been of the IgG type. There is now convincing evidence that the drug acts as a *hapten*. *In vivo*, the interaction between drug, antibody, and platelet leads to platelet injury and rapid sequestration; *in vitro*, it is manifested by various serologic phenomena, including platelet agglutination, lysis, and complement fixation. Neither the antibody nor the drug is active alone.

Numerous studies of platelet antibodies induced by quinidine, quinine, and Sedormid have provided evidence for an immunoreaction differing from that usually evident with hapten-induced antibodies (Fig. 34-5). In terms of a hypothesis proposed by Miescher and associates<sup>221, 222</sup> and by Shulman<sup>216, 474</sup> ("the innocent-bystander hypothesis"): (1) the antigen is a complex formed between the drug (hapten) and some plasma protein or other "carrier" molecule; (2) the antibody is directed against this drug-"carrier" complex, and not against any intrinsic antigenic determinant of the platelet; (3) the events leading to platelet injury involve a preliminary com-

bination between the drug and the antibody; (4) the resulting complex then attaches to the platelet by means of an essentially nonspecific process.

It is probable that degradation products of many drugs are responsible for sensitization,<sup>247</sup> a fact that may explain the absence of positive serologic reactions in many patients. In two patients with thrombocytopenia due to acetaminophen, the antibody was directed against a metabolite but not against the unaltered drug.<sup>172a,173</sup>

### Clinical Features

Thrombocytopenia of marked severity usually develops within 12 hours of ingestion of quinine, quinidine, or Sedormid by a sensitized individual. Gold salts and organic arsenicals may act more slowly.<sup>219</sup> Prodromal symptoms such as fever, chills, lethargy, and pruritus may be observed. Bleeding may be severe and usually is of abrupt onset. Hemorrhagic vesicles are commonly seen in the oral mucosa. A history may be obtained of prior ingestion of the drug followed by a latent period,<sup>223</sup> but this is not invariably the case. Exceedingly small amounts of drug may produce severe thrombocytopenia. For example, even the quinine present in tonic water may be sufficient ("cocktail" purpura).<sup>151</sup>

### Diagnosis

The megakaryocytes are normal in number, but there may be an increase in immature forms and platelet "budding" may be absent. In an occasional patient, transient hemolysis has been associated.<sup>474</sup>

Serologic verification of the presence of a platelet antibody may be made by a variety of techniques. In approximate order of sensitivity, those most commonly used are complement fixation,<sup>137,199,236</sup> "immunoinjury" techniques,<sup>61,231</sup> platelet agglutination, and inhibition of clot retraction.<sup>117,236</sup> The last named test is relatively insensitive,<sup>236</sup> but can be performed outside of an especially equipped laboratory, either during the acute phase or after the patient has recovered. Re-

cently developed methods employing platelet aggregometry (page 1054) also may prove to be suitable for the routine detection of platelet antibodies.<sup>170</sup>

The readministration of a suspected drug in an attempt to confirm an etiologic relationship is not recommended as a routine diagnostic measure.<sup>40</sup> Recurrences of severe thrombocytopenia may result unless exceedingly small amounts of drug (plasma concentrations on the order of  $10^{-6}$ ,  $10^{-7}$  M) are administered at a carefully controlled rate, such as by an automatic infusion pump.<sup>216</sup>

### Treatment

No therapy ordinarily is needed since withdrawal of the offending drug is followed by recovery. Platelet transfusions and exchange transfusion may be helpful in tiding the patient over life-threatening complications. There is little evidence that steroids are effective therapeutically, although they are widely used. When the responsible drug is quinidine, quinine, or Sedormid, thrombocytopenia usually begins to regress within 24 hours if no additional drug is taken. A normal platelet count is restored within one week, often to be followed by mild thrombocytosis. Thrombocytopenia that persists longer than two weeks is probably not due to a drug-induced platelet antibody, except in the case of drugs that are excreted very slowly. Thus, if the offending drugs are gold salts or arsenicals, protracted thrombocytopenia is the rule. BAL may accelerate excretion of these drugs.<sup>214,241,250</sup>

Although the titer of antibody may fall with time, potentially serious thrombocytopenia can be expected throughout the life of a sensitized individual, and further use of an offending drug is absolutely contraindicated.

### Miscellaneous Immunologic Thrombocytopenias

Thrombocytopenia may complicate various disorders known to be associated with disordered immunologic responses. In most

instances, it appears to result from immunologic platelet injury.

*Systemic lupus erythematosus* (SLE) may be manifested by thrombocytopenia months or even years before other manifestations of the disease appear.<sup>371,379,455</sup> Bleeding is rarely severe, and autoimmune hemolytic anemia is frequently associated. Platelet antibodies have been demonstrated in as many as 78% of these patients when the more sensitive tests have been used and are not uncommon in patients without thrombocytopenia.<sup>59,61</sup> In one series of patients, platelet survival was shortened and "megathrombocytes" were numerous,<sup>61</sup> observations suggesting the presence of compensated platelet destruction. "Amegakaryocytic" thrombocytopenia with normal platelet survival was reported in one patient with SLE.<sup>387</sup>

Other disorders in this category include certain autoimmune hemolytic anemias (Evans' syndrome),<sup>378,419</sup> chronic lymphocytic leukemia,<sup>171</sup> the lymphomas,<sup>371</sup> rheumatoid arthritis,<sup>61</sup> and hyperthyroidism.<sup>382,423,445</sup> Platelet antibodies are less commonly found in association with these disorders but may be present in the absence of thrombocytopenia.<sup>61</sup>

Thrombocytopenia may be associated with certain allergic reactions, eg, to foods,<sup>329,418,484</sup> insect bites,<sup>380</sup> tetanus toxoid,<sup>406</sup> and vaccines.<sup>294,299</sup> There is indirect evidence that platelet destruction results from an immunologic mechanism in these instances, possibly as a result of the action of antigen-antibody complexes<sup>103,487</sup> (page 1101). Diffuse intravascular coagulation (page 1211) may be an important contributory factor in the thrombocytopenia associated with heat stroke<sup>503</sup> or certain anaphylactic reactions.

### Deficient Platelet Production

Deficient platelet production may result from one of three mechanisms: (1) hypoplasia or suppression of the precursor megakaryocytes; (2) ineffective thrombopoiesis despite a normal precursor mass; or, rarely, (3) deficiency or aberration of thrombopoietic control mechanisms.

### Hypoplasia of Megakaryocytes

In uncomplicated marrow hypoplasia, platelet survival usually is normal, and thrombokinetic studies have revealed diminished "total" and "effective" thrombopoiesis.<sup>390</sup> A wide variety of exogenous factors and endogenous processes may lead to hypoplasia of the megakaryocytes and deficient platelet production. Such a process is characteristic of aplastic anemia and the Fanconi syndrome (Chapter 56). In both disorders, thrombocytopenia may be the first evidence of the disease,<sup>467</sup> and may persist after anemia and granulocytopenia have responded to treatment.<sup>470</sup>

Thrombocytopenia is uncommon in the myelophthisic processes (Chapter 57), but when present appears to result from deficient platelet production.<sup>396</sup> The mechanism by which infiltration of the bone marrow with abnormal cells impairs thrombopoiesis is unclear.<sup>272,348</sup> The number of megakaryocytes is difficult to assess accurately in most of these disorders, and quantitative studies of thrombokinetics are fragmentary.<sup>396</sup> In disseminated carcinoma, thrombocytopenia may accompany diffuse involvement of the bone marrow,<sup>499</sup> but thrombocytosis is more common. In some cases of thrombocytopenia associated with carcinoma, an immunologic process has been implicated.<sup>348</sup> As discussed elsewhere (page 1101), hypoplasia of the megakaryocytes with deficient platelet production is the major cause of the thrombocytopenia that occurs in association with certain viral infections.

In many of the above-mentioned disorders, factors other than deficient platelet production may complicate the picture.

### Chemical and Physical Agents

#### Agents That Produce Generalized Bone Marrow Suppression

Chemical and physical agents may produce thrombocytopenia as the result of a predictable suppression of the marrow, eg, ionizing radiation, alkylating agents, antimetabolites,

Dr. B. L. Shinn  
Ph.D. M.D.

cytotoxic drugs. The mechanisms by which these agents act are well defined (Chapter 55), and thrombocytopenia is a common complication when they are used in immunosuppression and in cancer chemotherapy. In addition, a larger number of drugs produce marrow hypoplasia as a result of idiosyncratic reactions, eg, chloramphenicol (Table 56-2, page 1746). The pathophysiology of thrombocytopenia in these cases is poorly understood.

Drugs of both types damage other bone marrow precursors as well as the megakaryocytes, and the usual picture is one of diffuse bone marrow hypoplasia and pancytopenia. Rarely, only thrombocytopenia may be present. The megakaryocyte is not insensitive to whole body irradiation (page 1714), and platelets frequently are the last cell type to return to normal following recovery from bone marrow hypoplasia; in some patients, thrombocytopenia may persist indefinitely.<sup>467,470</sup> Drug-induced aplastic anemia is discussed in Chapter 56.

#### *Agents That Selectively Suppress the Megakaryocyte*

*Chlorothiazide* and various of its congeners may produce thrombocytopenia by one of at least two mechanisms, ie, by the formation of platelet antibodies,<sup>142 172</sup> as already discussed, or by a poorly understood suppression of thrombopoiesis. The latter action is by far the more common. The evidence for marrow suppression rests largely on negative serologic tests for platelet antibodies and diminution in the number of megakaryocytes in the bone marrow. Mild asymptomatic thrombocytopenia may occur in as many as 25% of persons taking these agents, an observation suggesting that the thrombocytopenia may be a pharmacologic rather than an idiosyncratic effect.<sup>411</sup> In some cases, the thrombocytopenia may have been caused by severe congestive heart failure.<sup>411,445</sup> Recovery from thrombocytopenia in association with thiazide drugs is very slow, and readministration of the drug for protracted periods usually is required to reproduce thrombocytopenia.<sup>411</sup>

The administration of chlorothiazides to

pregnant women is a rare cause of congenital thrombocytopenia in the neonate.<sup>220,237</sup> The pathophysiologic mechanism apparently is suppression of the megakaryocytes. The mothers themselves are rarely, if ever, thrombocytopenic.<sup>142</sup>

*Estrogenic hormones* appear to affect platelet kinetics in animals both by facilitating reticuloendothelial sequestration<sup>438</sup> and by impairing thrombopoiesis.<sup>253</sup> Neither effect has been convincingly demonstrated in man, but several cases of "amegakaryocytic" thrombocytopenia have been reported following the administration of diethyl stilbestrol.<sup>164,256</sup> In one patient, thrombocytopenia recurred when the hormone was readministered.<sup>161</sup>

There is evidence that *ethanol* suppresses platelet production,<sup>212,213,232</sup> a phenomenon that may be a relatively common cause of mild thrombocytopenia in the alcoholic patient. In most reported cases, nutritional factors were excluded but hepatic function was impaired. Thrombokinetic studies have demonstrated accelerated platelet destruction as well as a subnormal compensatory increase in thrombopoiesis.<sup>360</sup> The megakaryocytes usually have been normal or even increased in number.<sup>212 232</sup> The experimental administration of ethanol produces thrombocytopenia in somewhat less than 50% of normal subjects.<sup>212,213 232</sup> Large doses were required and the duration of ethanol administration prior to the onset of thrombocytopenia ranged from hours<sup>232</sup> to weeks,<sup>213</sup> observations that suggest a component of individual idiosyncrasy. Bleeding is rare, and when ethanol is withdrawn the platelet count returns to normal or even supernormal levels in two to three weeks.<sup>212</sup>

*Corticosteroids* may suppress platelet formation in some patients with thrombocytopenia.<sup>24</sup> They have no clearcut effects on thrombopoiesis in normal subjects.<sup>115</sup>

#### **Congenital Megakaryocytic Hypoplasia**

The term "congenital megakaryocytic hypoplasia" includes a group of disorders having in common neonatal thrombocytopenia, marked hypoplasia of the megakaryo-

cytes, and congenital anomalies.<sup>391</sup> The similarity between the anomalies associated with this syndrome and those associated with congenital rubella suggests that the disorder is due to intrauterine fetal injury at approximately six to eight weeks of gestation.<sup>391</sup> Maternal ingestion of tolbutamide<sup>339</sup> was implicated in some cases, but with this exception no etiologic agents have yet been defined. There is evidence for a hereditary basis in some kindreds.<sup>391,468</sup>

Purpura and ecchymoses usually are apparent in these infants at birth, and serious bleeding manifestations, in particular intracranial bleeding, are not uncommon. Examination of the bone marrow reveals marked diminution in the number of megakaryocytes; in many patients they may be totally absent. A leukemoid reaction of the granulocytic type (page 1301) with myeloid hyperplasia of the marrow has been documented in as many as 50% of the patients.<sup>391</sup> These findings, as well as the platelet count, may fluctuate from time to time.<sup>391</sup>

Associated skeletal anomalies are present in virtually every subject. Bilateral agenesis of the radius is the most common.<sup>339,471</sup> In some of these infants the ulna and the humerus also are absent.<sup>370</sup> Less commonly, cardiac defects,<sup>370</sup> microcephaly,<sup>373,398</sup> micrognathia, and various other minor anomalies are seen.<sup>391</sup> Chromosome abnormalities have been demonstrated in an occasional patient, eg, trisomy D<sub>13</sub> and E 18.<sup>391</sup> Hereditary spherocytosis was associated in two cases.<sup>506</sup>

Diagnosis is rarely difficult, but the possibility of congenital rubella and some variants of the Fanconi syndrome (Chapter 56) should be excluded. Corticosteroids and splenectomy are therapeutically ineffective; treatment is mainly supportive. In a few patients, survival into adult life was associated with a gradual amelioration of the thrombocytopenia.<sup>391</sup> Early death, usually due to hemorrhage, is more common.

### Ineffective Thrombopoiesis

Thrombocytopenia is a consistent feature of *megaloblastic hematopoiesis* that results

from deficiency of vitamin B<sub>12</sub> or folic acid (Chapter 15). Although seldom severe and rarely of clinical significance, it is due to a distinctive abnormality of platelet production termed "ineffective" thrombopoiesis, which was first demonstrated by means of thrombokinetic studies (page 1103).<sup>45,396</sup> It is characterized by diminished platelet production despite the presence of an increased megakaryocyte mass, and is thus quite analogous to ineffective erythropoiesis, which is also characteristic of the megaloblastic anemias (Chapter 15).

Platelet production, whether calculated per megakaryocyte or per nuclear unit, is markedly diminished.<sup>396</sup> Although the number of megakaryocytes increases in response to thrombopoietic stimuli (Fig. 34-1), the normally concomitant increase in their volume does not occur<sup>45</sup> (Table 34-1) (Fig. 34-6). This presumably is due to impaired DNA synthesis and the consequent limitation in nuclear endoreduplication.<sup>401</sup> In stained smears, the megakaryocytes often appear hyperlobulated, and circulating platelets are abnormally large.

Moderate shortening of platelet survival time<sup>408</sup> and, rarely, hypoplasia of the megakaryocytes<sup>363</sup> may be important contributory factors in the production of thrombocytopenia in some cases.

Ineffective thrombopoiesis also has been described in the *Di Guglielmo syndrome*<sup>366</sup> and in *paroxysmal nocturnal hemoglobinuria*. In the latter disorder, a defect in the platelet membrane results in abnormal sensitivity to the action of various antibodies and of complement.<sup>2</sup> Nevertheless, platelet survival usually is normal, and the moderate thrombocytopenia commonly associated with this disorder appears to result from ineffective thrombopoiesis.<sup>396</sup> Ineffective thrombopoiesis also is present in some hereditary forms of thrombocytopenia,<sup>336,296</sup> thrombopoietin deficiency (as discussed below), and certain forms of "preleukemia."<sup>336</sup>

Moderate thrombocytopenia, which responds to the administration of iron, has been described in association with severe iron-deficiency anemia.<sup>388,420</sup> This may represent another form of ineffective thrombopoiesis, but

in some cases thrombocytopenia was more likely the result of coexistent folic acid deficiency.<sup>358</sup>

# Disorders of Thrombopoietic Control

Disorders of this type are uncommon but they are of unusual interest in that thrombocytopenia appears to result from abnormalities in the mechanisms that normally regulate platelet production.

## "Thrombopoietin" Deficiency

In one remarkable patient, thrombocytopenia appears to be the result of the deficiency of a humoral factor, possibly "thrombopoietin"<sup>326,473</sup> (page 386). The patient, now a young woman, has been studied continuously since she was discovered to have thrombocytopenia early in childhood. The transfusion of normal plasma has repeatedly induced the maturation of previously immature megakaryocytes, as well as an increase in platelet count to normal or even supernormal values. Neither corticosteroid therapy nor splenectomy has been therapeutically effective, but two spontaneous remissions of approximately one year's duration were observed. The clinical course has been complicated by one episode of hemolytic anemia of uncertain cause and another of glomerulonephritis. The patient remains responsive to plasma infusions at age 20. There is no evidence for a hereditary abnormality in this patient, but a similar syndrome has been described in several members of one kindred.<sup>495</sup>

## Unstable Thrombopoietic Regulation

There is indirect evidence that thrombopoiesis is controlled by a negative feedback mechanism which, when physiologically perturbed, may "oscillate" resulting in cyclic changes in platelet production<sup>428</sup> (page 386). Marked disturbances of this cyclic control mechanism may produce an exaggerated "oscillation," marked fluctuation in platelet production, and thrombocytopenia followed by thrombocytosis. At least two forms of thrombocytopenia as well as "rebound"

thrombocytosis (page 1107) have been attributed to this mechanism.

*Tidal platelet dysgenesis* is a rare condition characterized by thrombocytopenia and megakaryocytic hypoplasia that alternates with thrombocytosis and megakaryocytic hyperplasia at fixed intervals, usually 20 to 30 days.<sup>338,376</sup> Platelet survival is normal throughout this cycle,<sup>136,338</sup> even though thrombocytopenia may be severe in the "negative" phase. No therapy has proved effective.<sup>136,376</sup>

*Cyclic thrombocytopenia* is a more common disorder in which thrombocytopenia and thrombocytosis alternate at regular intervals, but are not accompanied by megakaryocytic hypoplasia in the "negative" phase. The disorder is most common in women, in whom thrombocytopenia develops during the menstrual period. Endocrine factors do not appear to be responsible.<sup>483</sup> Bleeding is seldom significant and there is no effective therapy.

A cyclic though irregular variation in the platelet count has been observed in thrombocytopenia caused by accelerated platelet destruction,<sup>315</sup> eg, ITP, and in children with cyanotic congenital heart disease.<sup>386</sup>

## Thrombocytopenia Due to Abnormal Platelet Pooling

### Disorders of the Spleen

The splenic platelet pool normally contains approximately one third of the total platelet mass (Chapter 9) (Fig. 34-1) and may increase as the result of a large variety of disorders having in common splenomegaly,<sup>323,339,400a</sup> eg, cirrhosis with portal hypertension,<sup>488</sup> sarcoidosis,<sup>369,451</sup> Gaucher's disease,<sup>342,425</sup> Hodgkin's disease and other lymphomas,<sup>351</sup> Felty's syndrome.<sup>392</sup> This may result in thrombocytopenia in the circulating blood despite a normal or even increased total platelet pool<sup>396,412</sup> (Table 34-1).

The mechanism of platelet sequestration in disorders associated with splenomegaly is poorly understood. Large numbers of platelets are found in spleens removed surgically, but histologic studies have not clarified the hemodynamic basis for platelet sequestration.

In contrast to the sequestration of *damaged* platelets in disorders such as ITP, the sequestration in these conditions is not an irreversible process; epinephrine administration mobilizes approximately the same proportion of the splenic platelet pool whether the spleen is normal in size or enlarged.<sup>3,45,418</sup> In portal hypertension, the platelet count is not correlated with the portal venous pressure, nor does the thrombocytopenia invariably respond to successful shunting procedures.<sup>488</sup> The role of hypervolemia in the production of thrombocytopenia in these disorders has not been well studied.<sup>359</sup>

There is evidence for accelerated platelet destruction in most instances of thrombocytopenia associated with disorders of the spleen.<sup>396</sup> The initial recovery of isotopically labeled platelets in the circulation of such patients is markedly reduced.<sup>331,332</sup> Platelet survival usually is moderately shortened<sup>396,408</sup> although it may be normal.<sup>356</sup> Thus platelet pooling, even if an essentially passive process, is not entirely innocuous.

The clinical picture in "hypersplenic" thrombocytopenia usually is dominated by the underlying disease, and numerous other abnormalities of hemostasis and coagulation may be present, eg, in cirrhosis (Table 38-2, page 1207). The usual picture is one of pancytopenia, with relatively mild thrombocytopenia, and normal or moderately increased numbers of megakaryocytes in the bone marrow. In general, the severity of the thrombocytopenia correlates poorly with the size of the spleen, but it is nonetheless difficult to entertain the diagnosis of thrombocytopenia due to abnormal splenic platelet pooling in the absence of significant splenic enlargement.<sup>412</sup>

Therapy is seldom indicated for thrombocytopenia alone, but splenectomy sometimes alleviates the pancytopenia completely.<sup>450,433</sup> (Chapter 45).

### Hypothermic Anesthesia

Platelets become more "sticky," swell, and undergo various morphologic changes when stored *in vitro* at temperatures below 37°C.

This usually is a reversible process, but clumping, release of ADP, and irreversible aggregation follow protracted chilling.<sup>349</sup> Similar changes *in vivo* may underlie the thrombocytopenia that is associated with hypothermic anesthesia.

In man, mild, reversible thrombocytopenia is a predictable consequence of hypothermia below 25°C, and is usually of no clinical consequence.<sup>496</sup> In an occasional patient, thrombocytopenia persists following rewarming and may produce hemorrhage.<sup>341</sup> In some children subjected to deep hypothermia, brain damage was attributed to *in vivo* platelet clumping.<sup>341</sup> Heparin administration appears to minimize the fall in the platelet count,<sup>498</sup> but its therapeutic value is uncertain.<sup>341</sup> Many other factors must be considered in such cases, eg, extracorporeal circulatory devices, massive transfusion, intravascular coagulation.

## Miscellaneous Forms of Thrombocytopenia

### Nonimmunologic Platelet Destruction

Thrombocytopenia commonly is the result of accelerated utilization or destruction of platelets by various nonimmunologic processes. Disorders in this category (Table 34-3) are discussed elsewhere, ie, diffuse intravascular coagulation including the Kasabach-Merritt syndrome (giant hemangioendotheliomas) (Chapter 38); fibrinogenolysis (Chapter 38); thrombotic thrombocytopenic purpura and various other microangiopathic processes<sup>483a,497a</sup> (Chapter 28). Thrombocytopenia due to platelet damage by infectious agents is discussed elsewhere in this chapter (page 1101).

*Ristocetin*, a drug no longer used therapeutically, produces thrombocytopenia by a unique direct toxic action on the platelets.<sup>180,198</sup> It may also interact with the "anti-bleeding" factor that is lacking in von Willebrand's disease (page 1179).<sup>198</sup> Data suggesting that intravenous heparin administration produces thrombocytopenia by a similar mechanism<sup>182</sup> have not been confirmed.<sup>167,233,462</sup>

Thrombocytopenia, with platelet counts in the range of 50 to  $100 \times 10^9/l$ , is a predictable sequel of surgical procedures employing various extracorporeal circulatory devices.<sup>463,466</sup> It results from platelet injury during passage through the pump, and with modern equipment is no longer a major problem. Thrombocytopenia in such patients can be treated by the administration of fresh blood or platelet concentrates, but is rarely associated with significant bleeding. The presence of severe thrombocytopenia and bleeding following extracorporeal circulation suggests a complicating factor.

### Hereditary Thrombocytopenias

Hereditary forms of thrombocytopenia with diverse genetic, clinical, and laboratory features have now been documented in numerous kindreds (Table 34-6). For convenience, those forms in which abnormalities of platelet function appear to be the major feature are discussed in Chapter 35, eg, thrombopathic thrombocytopenia, the Bernard-Soulier syndrome. The Wiskott-Aldrich syndrome is discussed in Chapter 44.

Thrombocytopenia is a consistent feature of many hereditary disorders that are better known for associated abnormalities. Those involving the hematopoietic system are discussed in detail elsewhere, eg, the May-Hegglin anomaly (Chapter 42),<sup>395</sup> the Chediak-Steinbrink-Higashi anomaly (Chapter 42), hemoglobin Köln (Chapter 24),<sup>432</sup> and the Fanconi syndrome and variants thereof (Chapter 56).<sup>436</sup> In one kindred, thrombocytopenia inherited as an X-linked recessive trait was associated with increased levels of IgA immunoglobulins and renal disease.<sup>390</sup> Hereditary thrombocytopenia associated with various aminoacidurias and other inborn errors of metabolism has only recently been recognized and is of unusual interest (Table 34-6). Virtually nothing is known concerning the cause of thrombocytopenia in these conditions, and there is no known treatment. It is noteworthy that some aminoacidurias may be associated with a thromboembolic diathesis, eg, homocystinuria.<sup>372</sup>

Table 34-6. The Hereditary Thrombocytopenias

<b>I X-LINKED RECESSIVE INHERITANCE</b>	
A	Wiskott Aldrich syndrome and variants thereof (Chapter 44)
B	"Isolated" thrombocytopenia <sup>353,464</sup>
C	Thrombocytopenia with increased IgA immunoglobulins and renal disease <sup>390</sup>
<b>II AUTOSOMAL DOMINANT INHERITANCE</b>	
A	"Thrombopathic" thrombocytopenia
B	"Isolated" thrombocytopenia <sup>267,340,465</sup>
C	Varieties in which thrombocytopenia is a feature of a generalized disorder (May-Hegglin anomaly, <sup>337,365</sup> hemoglobin Köln <sup>399,452</sup> )
<b>III AUTOSOMAL RECESSIVE INHERITANCE</b>	
A	Dystrophic thrombocyteaire hemorrhagipare (Bernard-Soulier syndrome)
B	Varieties in which thrombocytopenia is a feature of a generalized disorder
1	Chediak-Steinbrink-Higashi anomaly (page 1323)
2	Fanconi syndrome and variants thereof (page 1767)
3	Inborn errors of metabolism (cystathioninuria <sup>427</sup> hyperglycinemia <sup>431,440</sup> methylmalonic and isovaleric acidemia <sup>431</sup> Sidbury syndrome <sup>422</sup> Schwachman syndrome <sup>481</sup> )
<b>IV UNCLASSIFIED FORMS</b>	
A	In association with platelet antibodies <sup>343,397</sup>
B	In association with abnormalities of platelet function <sup>454,461,469,473,485</sup>
C	In association with other heritable hemostatic defects (von Willebrand's disease, <sup>439</sup> factor IX deficiency <sup>397</sup> )
D	Miscellaneous <sup>335</sup>

Hereditary thrombocytopenia not associated with ancillary clinical or laboratory manifestations has been well documented ("isolated" hereditary thrombocytopenia). This may be inherited either as an X-linked recessive trait<sup>353,464</sup> or as an autosomal dominant trait. The latter form appears to be the more common.<sup>340,433,436</sup> The clinical laboratory features are essentially the same in both forms. Bleeding is mild and in some instances the affected family members are virtually asymptomatic.<sup>340,391,502</sup> Platelet function appears to be normal.<sup>436</sup> Megakaryocytes are normal in number, but quantitative studies of thrombopoiesis have not been reported. In one kindred,<sup>433</sup> shortened platelet survival due to an intracorporeal platelet abnormality was demonstrated.

Several other reports of hereditary thrombocytopenia do not provide sufficient data for definite classification.<sup>335</sup> In some patients the presence of platelet antibodies was described<sup>397</sup>; in others, poorly documented abnormalities of platelet function,<sup>456,461,469,472,482</sup> or additional inherited abnormalities of hemostasis or blood coagulation<sup>397,439,454</sup> were associated.

### Thrombocytopenia in Association with Infections

Purpura was recognized as a manifestation of pestilential fevers 2000 years ago. It is now known that bleeding in association with infections may be caused by several factors, among which thrombocytopenia is the most common (Table 34-2).

#### Viruses

Viral infections may produce thrombocytopenia by at least three mechanisms: (1) impaired platelet production as a result of invasion of the megakaryocytes by the virus; destruction of circulating platelets by (2) the virus, or (3) viral antigen-antibody complexes.

The administration of *live measles vaccine* produces significant though subclinical thrombocytopenia in the majority of normal children.<sup>306</sup> Degenerating, vacuolated megakaryocytes were seen three days after administration of the vaccine, at which time plasma levels of acid phosphatase were subnormal. The nadir of the platelet count was reached seven days after vaccination. These data, and studies of other viruses in animals, are consistent with the hypothesis that deficient platelet production due to parasitization of the precursor cell is a major factor in the production of thrombocytopenia. This hypothesis gains further support from *in vitro* studies demonstrating rapid viral replication within megakaryocytes.<sup>272,293,362</sup> Morphologic abnormalities of the megakaryocytes also have been described in Thai hemorrhagic fever.<sup>27,313</sup>

In other viral infections, there is indirect evidence that platelet damage results from interaction between the virus and the platelets

in the circulating blood, although damage to megakaryocytes also may be significant. Thus, in influenza and rubella,<sup>262</sup> mild thrombocytopenia has been documented during the acute febrile phase of the disease. In *in vitro* studies have demonstrated adsorption or "phagocytosis" of viruses by human platelets.<sup>316,318</sup> Such viruses produce platelet aggregation and the release reaction *in vitro*<sup>292</sup> and cause marked thrombocytopenia with reduced platelet survival in experimental animals.<sup>318</sup>

Although mild thrombocytopenia is a predictable effect within one week following the administration of live measles vaccine, in some subjects thrombocytopenia of greater severity develops two to four weeks later,<sup>293,296</sup> at a time when neither megakaryocyte damage nor acute viremia is a likely explanation. A similar phenomenon occurs in the spontaneous disease, and in rubella.<sup>304</sup> In the latter disorder, the titer of antibodies capable of inducing platelet aggregation in the presence of "small-sized" rubella antigen was much higher in children who developed thrombocytopenia following spontaneous rubella infection than in similar patients without thrombocytopenia.<sup>304</sup> This has led to the hypothesis that a viral antigen-antibody complex is responsible for platelet sensitization and sequestration.<sup>304</sup> Antigen-antibody complexes are known to induce platelet aggregation<sup>303</sup> and the release reaction *in vitro*, as well as thrombocytopenia when administered to experimental animals.<sup>302,318,432</sup> This mechanism may also explain many instances of "acute ITP" which develop following recovery from viral infections (page 1079).

Of newborns with congenital rubella, 40 to 80% are thrombocytopenic.<sup>267,276,309,314</sup> In addition to the other stigmas of this syndrome,<sup>422</sup> hepatomegaly and splenomegaly usually are present. Rarely, thrombocytopenia is the only manifestation.<sup>267,442</sup> Megakaryocytes frequently are decreased in number, and rarely may be totally absent, an observation that suggests deficient platelet production.<sup>269</sup> Schistocytes and other evidence of DIC are present in many of these infants.<sup>267,311,324</sup>

In *infectious mononucleosis* (IM),<sup>263,273</sup> subclinical thrombocytopenia is not uncommon. In the rare patient in whom severe thrombocytopenia and bleeding develop,<sup>310</sup> the diagnosis of acute leukemia may be mistakenly made. In some patients with IM, antibodies directed against a specific platelet antigen (small "i") have been demonstrated. They appear to act as platelet cold agglutinins both in vitro and in vivo (Chapter 43).

### Bacteria

Thrombocytopenia that develops in association with most severe bacterial infections is the result of DIC (Chapter 38), but other factors also may play a role. Platelet utilization on damaged vascular surfaces may be important in some cases, eg, meningococcemia.<sup>313</sup> Certain bacterial toxins, including exotoxins<sup>270,294</sup> and endotoxins,<sup>278,286a,289,293a,298</sup> produce thrombocytopenia in experimental animals, but the role of such toxins in man is uncertain.<sup>435</sup> (Chapter 38). Direct interaction between bacteria and platelets in the circulation has been demonstrated experimentally.<sup>353</sup>

### Post-transfusion Thrombocytopenia

Although brisk external hemorrhage in the absence of blood replacement usually produces thrombocytosis (page 1107), moderate thrombocytopenia commonly follows massive blood transfusions in such cases<sup>400</sup> (Chapter 11). Post-transfusion thrombocytopenia of this type is a predictable result of the transfusion of large amounts of stored whole blood, and should not be confused with that due to platelet isoantibodies (page 1091). Various factors have been implicated in the pathogenesis of this phenomenon, including the presence of a platelet clumping factor in the plasma of stored blood and platelet utilization due to embolic occlusion of the microvasculature by platelet clumps.<sup>402,424</sup> The observation that the magnitude of thrombocytopenia varies in direct proportion to the volume of blood administered<sup>410</sup> favors the view that post-transfusion thrombocytopenia

is mainly the result of the external loss of viable platelets and their replacement with nonviable platelets in stored blood. Following this "washout" phenomenon, the platelet count returns to normal slowly, ie, within three to five days, and the phenomenon is thus entirely similar to the effects of experimental thrombocytapheresis or plasmapheresis.<sup>115,361</sup> A similar process presumably explains the mild thrombocytopenia that may follow exchange transfusion, eg, in erythroblastosis fetalis.<sup>366,367</sup>

Post-transfusion thrombocytopenia seldom produces significant bleeding but can be prevented by the use of 1 unit of fresh blood for every 5 units of stored blood, and can be treated by platelet transfusions. The sequelae of occlusion of the microvasculature by platelet emboli from stored blood are probably of greater clinical significance than is bleeding.<sup>308,476</sup> The numerous other factors that may produce thrombocytopenia in association with massive hemorrhage should also be kept in mind, particularly DIC.

### Other Forms of Thrombocytopenia

Thrombocytopenia is common in cirrhosis, but is relatively rare in other types of liver disease.<sup>381</sup> Isolated thrombocytopenia in the absence of coagulation abnormalities is not uncommon in inactive cirrhosis.<sup>350</sup> The major pathophysiologic factor may be splenic platelet pooling due to portal hypertension, but, as discussed above, this remains poorly understood.<sup>488</sup>

It is generally agreed that the major cause of bleeding in *uremia* is a qualitative abnormality in platelet function (page 1129), but thrombocytopenia has been documented in as many as 50% of patients<sup>351,417,451</sup> and in some this appeared to be the major cause of bleeding.<sup>437</sup> There is surprisingly little information concerning the pathophysiology of this manifestation, and the effects of uremia on thrombopoiesis have not been defined. In some disorders associated with uremia, DIC may be present (Chapter 38).

Reports of thrombocytopenia in association with several disorders not discussed above are listed in Table 34-2. For further

details concerning these uncommon causes of thrombocytopenia, the reader is referred to the original papers.

## Thrombocytosis

Thrombocytosis refers to the presence of an abnormally high number of platelets in the circulating blood; it may result from the various pathologic processes and physiologic stimuli summarized in Table 34-7. It is a common feature of the various "myeloproliferative" syndromes such as polycythemia vera (Chapter 30), chronic myelocytic leukemia (Chapter 48), and myelofibrosis (Chapter 57). In these disorders, increased platelet numbers may be a significant pathophysiologic feature in the production of hemorrhage, thrombosis, or both. An elevated platelet count also is commonly associated with various infectious, inflammatory, and neoplastic disorders. In these conditions, the increased platelet numbers seldom produce symptoms, but often are of considerable diagnostic significance. The unqualified term "thrombocytosis" frequently is used with reference to these secondary or reactive forms.<sup>559</sup>

### Pathophysiology

Transitory thrombocytosis may result from the mobilization of extravascular platelet pools, eg, following epinephrine administration<sup>511</sup> or vigorous exercise.<sup>532</sup> Such "physiologic thrombocytosis" is discussed on page 388. All other forms of thrombocytosis apparently are the result of accelerated platelet production. Preliminary thrombokinetetic data would suggest that this may result from two different mechanisms (Table 34-8). In patients with reactive or secondary thrombocytosis, as in the normal person, the platelet count is directly correlated with the megakaryocyte mass and is inversely correlated with the mean megakaryocyte volume (Fig. 34-6). This is the result of regulatory processes that normally reduce the stimulus to nuclear endoreduplication as the platelet count rises (Chapter 9).<sup>395,396</sup> The factors leading to accelerated platelet production in

**Table 34-7. Causes of Thrombocytosis**

- I **PHYSIOLOGIC** (exercise, parturition, epinephrine)
- II **DISORDERS OF THE HEMATOPOIETIC SYSTEM**
  - A "Myeloproliferative syndromes" (thrombocythemia, polycythemia vera, chronic myelocytic leukemia, myelofibrosis)
  - B Rapid blood regeneration (following hemorrhage in various hemolytic anemias)
  - C "Rebound" thrombocytosis (following recovery from thrombocytopenia or marrow suppression)
  - D Miscellaneous (iron-deficiency anemia, hemophilia, tidal platelet dysgenesis)
- III **ASPLENIC STATES** (following splenectomy; splenic agenesis and atrophy, splenic vein thrombosis)
- IV **INFECTIOUS AND INFLAMMATORY DISEASES** (many acute infections, many chronic infections, particularly osteomyelitis, tuberculosis, ulcerative colitis, regional enteritis, rheumatoid arthritis, acute rheumatic fever, sarcoidosis, cirrhosis of the liver, Wegener's granulomatosis)
- V **NEOPLASMS** (various carcinomas, Hodgkin's disease and other lymphoreticular disorders)
- VI **MISCELLANEOUS** (following trauma and surgical procedures, osteoporosis, nephrotic syndrome and other forms of chronic renal disease, renal cysts, Cushing's disease, glycogen storage disease)

the various disorders associated with reactive thrombocytosis are almost totally obscure.

In *autonomous thrombocytosis*, platelet production apparently is unresponsive to normal regulatory processes, the platelet count does not correlate with the megakaryocyte volume (Table 34-8, Fig. 34-6).<sup>395,396</sup> and the decrease in megakaryocyte size normally resulting from an increase in the circulating platelet mass is not seen. Autonomous thrombocytosis has been likened to neoplastic proliferation of other hematopoietic elements,<sup>542</sup> and has been demonstrated in thrombocythemia and in polycythemia vera.<sup>554a</sup> Preliminary studies have led to the somewhat surprising conclusion that accelerated platelet production in chronic myelocytic leukemia is not autonomous.<sup>396,563</sup> (Chapter 48).

### Thrombocythemia

Thrombocythemia (primary, essential, hemorrhagic, or idiopathic thrombocythemia)

Fig. 34-6 Thrombokinetics in autonomous thrombocytosis. The expected relationship between megakaryocyte volume and the circulating platelet count as shown by the solid line is not seen in two clinical settings. In megaloblastosis the limitation of nuclear replication appears to restrict endomitosis, and hence megakaryocyte volume, despite the thrombocytopenia. In contrast megakaryocyte volume is increased in thrombocythemia (primary thrombocytosis) due to the autonomous endoproliferation. (From Harker,<sup>395</sup> courtesy of the author, the International Academy of Pathology and William & Wilkins Company.)

is characterized by abnormal proliferation of the megakaryocytes. It is manifested clinically by bleeding and a thromboembolic diathesis.<sup>530,542-571</sup> The disorder is rare, is

most frequently seen in persons in middle adult life, and affects men and women with equal frequency.<sup>542</sup> Thrombocythemia belongs in the spectrum of "myeloproliferative" disorders,<sup>560</sup> a concept that is discussed elsewhere (Chapter 46).

### Pathophysiology

Thrombocythemia is the prototype of "autonomous" thrombocytosis, discussed above. Marked increases in megakaryocyte number, total megakaryocyte mass, and mean megakaryocyte volume are characteristic<sup>395,396</sup>; platelet production may be increased to as much as 15 times normal.<sup>396</sup> The life span of platelets usually is normal<sup>395,396,565,565</sup>, reports of prolonged platelet survival<sup>509</sup> have not been confirmed.<sup>396,511,570</sup> Shortened platelet survival has been demonstrated in a few cases,<sup>334</sup> and may be the result of platelet destruction in the spleen (page 1098).

The mechanisms by which marked expansion of the circulating platelet mass produces either hemorrhage or thrombosis have not been defined.<sup>533</sup> There is preliminary evidence that the major factor in the production of hemorrhage is an intrinsic qualitative abnormality of platelet function, possibly an abnormality of the release reaction. The re-

Table 34-8. Differentiation of Thrombocythemia and Reactive Thrombocytosis

	Reactive Thrombocytosis	Thrombocythemia
<b>THROMBOKINETIC FEATURES</b>		
Total megakaryocyte mass	Slightly increased	Greatly increased
Megakaryocyte number	Increased	Increased
Megakaryocyte volume	Decreased	Increased
Platelet turnover or production rate	Increased	Increased
Total platelet mass	Increased	Increased
Platelet survival	Normal	Normal to slightly decreased
<b>CLINICAL AND LABORATORY FEATURES</b>		
Thromboembolism and hemorrhage	Uncommon	Common
Duration	Often transitory	Usually persistent
Splenomegaly	Absent*	Present in 80% of cases
Platelet count	Usually $< 1,000 \times 10^9/l$	Usually $> 1,000 \times 10^9/l$
Bleeding time	Usually normal	Often prolonged
Platelet morphology and function	Usually normal	Often abnormal
Leukocyte count	Usually normal*	Increased in 90% of cases

\*Unless as the result of the underlying disorder  
Thrombokinetetic data from Harker.<sup>395,396,545</sup>

ported findings have varied greatly from patient to patient, however, and are discussed in Chapter 35.<sup>557,566</sup> Most evidence would suggest that *thrombosis* is the consequence of the greatly increased platelet mass, together with a qualitative abnormality of the platelets.<sup>559,591</sup> The role of platelets in the pathophysiology of thrombosis is discussed in Chapter 39.

### Clinical Picture

Recurrent gastrointestinal hemorrhage<sup>580</sup> and epistaxis are the most common bleeding manifestations,<sup>516,542</sup> although hazardous hemorrhage may follow trauma or surgical operations, including even trivial biopsy procedures. Easy bruising is not uncommon, but petechiae are rarely seen.

Thrombosis of both veins and arteries may develop, and vessels in unusual sites are frequently involved, eg, the hepatic veins,<sup>539</sup> mesenteric vessels, axillary artery,<sup>539</sup> the veins of the penis with resulting priapism,<sup>542</sup> the digital vessels with resulting ischemic lesions of the toes.<sup>521</sup> Occlusion of the splenic vein<sup>542</sup> appears to be particularly common. Pulmonary embolism may follow thrombosis in any location, and is a frequent complication.

Significant splenomegaly is found in approximately 80% of these patients.<sup>542</sup> Splenic atrophy and infarction have been documented in several subjects, however.<sup>513,561,583</sup> Hepatomegaly of moderate degree is not uncommon, but lymphadenopathy is rare.

Peptic ulcer disease<sup>574</sup> and varices of the gastric and esophageal veins are not uncommonly associated with thrombocythemia<sup>513,543</sup>; rarely the signs and symptoms of secondary gout are seen.<sup>526</sup>

The clinical course of thrombocythemia is quite variable, and episodes of bleeding or thrombosis often are followed by long periods during which the patient is free of symptoms. In some cases, a benign course over a period of years has been documented despite very high platelet counts.<sup>536</sup> Thromboembolic complications are the usual cause of death.<sup>583</sup>

### Laboratory Findings

In the majority of patients with thrombocythemia, the platelet count exceeds  $1,000 \times 10^9/l$ , and counts as high as  $14,000 \times 10^9/l$  have been recorded.<sup>536,542</sup> As a consequence, platelet enumeration is often inaccurate. The determination of the volume of packed platelets (page 373) provides a useful semiquantitative method of measuring platelet numbers in this disorder. In stained blood smears, the platelets usually are clumped into large masses. Abnormalities of size, shape, and structure often are striking, eg, heavy granulation, "giant" forms, bizarre abnormalities of shape. Microcytosis of the platelets also has been described.<sup>520</sup> Megakaryocyte fragments may be present in the blood.

Morphologically the *erythrocytes* are usually normal.<sup>542</sup> Anemia, if present, usually is of the hypochromic, microcytic type,<sup>542</sup> and presumably is the result of chronic blood loss and iron deficiency. Slight erythrocytosis is present in approximately 30% of the patients.<sup>542</sup> Thrombocythemia was associated with pure red cell aplasia in one patient.<sup>517</sup> Howell-Jolly bodies and target cells may be seen in the blood smear in subjects with splenic atrophy.<sup>561</sup>

The *leukocytes* are increased in number, the total count usually ranging from 15.0 to  $40.0 \times 10^9/l$ . The differential count reveals neutrophilia and a "shift to the left," with band and juvenile metamyelocytes predominating. Occasionally myelocytes may be seen, but more immature forms are uncommon. Slight eosinophilia and basophilia are frequently present.

The *bone marrow* reveals marked hyperplasia of the megakaryocytes, which often appear in clumps or sheets.<sup>560</sup> Structural abnormalities of these giant cells and immature forms have been noted in some instances.<sup>520</sup> Hyperplasia of the granulocyte or erythrocyte precursors is not uncommon. In a few cases, myeloid metaplasia of the spleen, liver, lymph nodes, and kidneys and various minor chromosomal abnormalities have been described.<sup>539,587</sup> No characteristic histologic

picture has been noted in the spleen. Levels of leukocyte and platelet<sup>510</sup> alkaline phosphatase and serum levels of uric acid<sup>539</sup> and vitamin B<sub>12</sub> usually are elevated.<sup>526</sup>

The presence of massive numbers of platelets produces *pseudohyperkalemia*<sup>546</sup> and spurious increases in the serum levels of several other substances. These include acid phosphatase,<sup>529-530</sup> zinc,<sup>537</sup> lactic acid dehydrogenase,<sup>522</sup> acid mucopolysaccharides,<sup>552</sup> inorganic phosphorus,<sup>537</sup> and uric acid.<sup>539,546</sup> Marked thrombocytosis may lead to falsely high erythrocyte counts and grossly erroneous red cell indices when some automated counting devices are used.

Screening tests of blood coagulation usually reveal no abnormalities, but laboratory evidence of "hypercoagulability" (page 1237) is not uncommon. Signs suggesting low-grade intravascular coagulation also may be present.<sup>556</sup> The bleeding time may be prolonged or normal.<sup>562</sup> Abnormalities evidenced by tests of specific platelet functions are discussed on page 1130.

## Differential Diagnosis

Because of the magnitude and duration of the thrombocytosis and the usual ancillary findings, the differentiation of thrombocythemia from various other forms of thrombocytosis is rarely difficult (Table 34-8). In thrombocythemia, the platelet count usually exceeds  $1,000 \times 10^9/l$ , a finding that is relatively uncommon in the other forms. In many forms of reactive thrombocytosis, the elevation in the platelet count is transitory or persists for a matter of days or weeks only. Thrombocytosis persisting for months or years, unless treatment is given, is characteristic of thrombocythemia. Splenomegaly, hemorrhage, thrombosis, or morphologic or functional abnormalities of platelets are uncommon in the secondary forms unless they are the result of the underlying disease. In an occasional patient with cirrhosis of the liver, the presence of splenomegaly, varices, gastrointestinal bleeding, and thrombocytosis may lead to confusion with thrombocythemia.

Differentiation between thrombocythemia and polycythemia vera may be difficult, and in many cases this distinction appears to be largely semantic. Marked elevations of the hematocrit value in association with the signs<sup>543</sup> and symptoms of expanded blood volume, which characterize polycythemia vera, are uncommon in thrombocythemia.

## Treatment

Definitive therapy of primary thrombocythemia is directed at lowering the platelet count. <sup>32</sup>P-phosphate has been used successfully for this purpose for many years.<sup>559</sup> In appropriate doses, this isotope reduces the platelet count to desired levels with minimal side effects. Alkylating agents, such as melphalan<sup>513</sup> and busulfan,<sup>553</sup> and antimitotic drugs have also been widely used.<sup>560,574,575</sup> These agents may be administered on an intermittent schedule, use of the drug being discontinued when the platelet count falls to an approximately normal value and reinstituted when it rises again. A maintenance schedule may be more effective.<sup>513,542</sup> Because of the relatively long time required for the therapeutic effects of either <sup>32</sup>P or alkylating agents (two to six weeks), thrombocytapheresis has been recommended when an immediate reduction in the platelet count is required, eg, in serious hemorrhage or prior to a surgical operation.<sup>573</sup>

Anticoagulants such as heparin and coumarins (Chapter 39) have been widely used for the prevention and treatment of thromboembolic complications in thrombocythemia. Experience with these agents has been encouraging in some cases, disappointing in others.<sup>574</sup> When marked thrombocytosis is present, unusually high doses of heparin may be required.<sup>524,574</sup> Preliminary results with aspirin and other inhibitors of platelet function have been encouraging,<sup>578</sup> but these agents have not been thoroughly evaluated.

Splenectomy usually is contraindicated in thrombocythemia. In many subjects, uncontrollable rises in the platelet count and fatal complications have followed this procedure.<sup>513,514</sup> In certain instances, splenectomy

appeared to have "unmasked" previously latent thrombocythemia.<sup>513</sup>

## Reactive Thrombocytosis

Reactive thrombocytosis usually is moderate in degree, asymptomatic, short-lived, and responds to treatment of the underlying disorder (Table 34-8). Reactive thrombocytosis with the platelet counts above  $1,000 \times 10^9/l$  may be found in an occasional patient in whom two or more factors leading to thrombocytosis are concomitantly present, eg, inflammatory disease and iron deficiency.<sup>535</sup> In the vast majority of patients with reactive thrombocytosis, treatment directed at lowering the platelet count is not indicated.

### Post-splenectomy

Thrombocytosis is a predictable finding following splenectomy, but, contrary to the common impression, it does not necessarily develop immediately after this operation. A rising platelet count is first noted two to ten days after splenectomy, and usually reaches a peak one to three weeks later. Platelet counts in excess of  $1,000 \times 10^9/l$  are not uncommon.<sup>579</sup> The magnitude of post-splenectomy thrombocytosis is thus much greater than that which could result merely from the removal of the physiologic splenic platelet pool (page 385)<sup>331</sup>; a poorly understood increase in platelet production presumably is responsible. The observation that platelet levels of 5-hydroxytryptamine are subnormal in patients with reactive thrombocytosis following splenectomy remains unexplained.<sup>550,562</sup> Other evidence of platelet dysfunction has not been documented in such cases. The platelet count usually returns to normal levels in time, but several weeks or months may be required. Thromboembolic complications or hemorrhagic phenomena are rare in hematologically normal patients,<sup>531,548,549</sup> and there is little evidence to favor routine anticoagulation following splenectomy.<sup>579</sup>

When splenectomy is performed for the treatment of anemia, postoperative thrombocytosis often is marked, but the platelet count

usually falls to approximately normal levels if the anemia is completely corrected by the operation.<sup>549</sup> However, thrombocytosis often persists if anemia is not relieved.<sup>549</sup> In such patients, serious hemorrhage, thromboembolic manifestations, or both sometimes develop following splenectomy.<sup>526,548</sup> Treatment of the anemia by other measures may result in a reduction in the platelet count; if these measures are ineffective, and if the platelet count remains above  $1,000 \times 10^9/l$  and clinical manifestations result, therapy directed at lowering the platelet count, as described above, has been recommended.<sup>512</sup>

### Accelerated Hematopoiesis

Accelerated thrombopoiesis commonly is associated with accelerated erythropoiesis. Thus, increased platelet numbers are present in patients with various hemolytic anemias,<sup>556</sup> following acute blood loss,<sup>534,551,558</sup> and in some patients with secondary polycythemia associated with renal tumors<sup>518</sup> or congenital heart disease. The persistence of post-splenectomy thrombocytosis in anemic patients has been discussed above. Despite the evidence that "thrombopoietin" and erythropoietin are different substances<sup>554</sup>, these findings suggest that there is some interrelationship between erythropoietic and thrombopoietic control mechanisms<sup>549</sup> (page 386).

Thrombocytosis may be the result of "overshoot" or "rebound" phenomena<sup>569</sup> in several situations. Thus, increased platelet numbers are common findings in patients who have recovered from marrow suppression or thrombocytopenia of various types,<sup>568</sup> eg, suppression or thrombocytopenia due to alcohol,<sup>512</sup> pernicious anemia,<sup>568</sup> viral infections. Thrombocytopenia, followed by thrombocytosis when the drugs have been withheld, is a predictable effect of certain folic acid antagonists<sup>569,582</sup> and other antimitotic agents. Vincristine may specifically stimulate platelet production.<sup>573,576,577</sup> In tidal platelet dysgenesis (page 1098), thrombocytosis alternates with thrombocytopenia in a predictable cycle.

## Miscellaneous

Moderate thrombocytosis that persists for one to two weeks is commonly present one to two days after major *trauma* or *surgical operations*.<sup>519,527,572</sup> Thrombocytosis is common in pregnancy and the puerperium; this is discussed on page 388. In hemophilia, thrombocytosis may follow acute hemorrhage, but a moderate elevation of the platelet count frequently persists in the absence of bleeding.<sup>515</sup> *Iron-deficiency anemia* may sometimes be associated with thrombocytopenia (page 1097), but slight thrombocytosis is a more common finding.<sup>581</sup> Platelet counts are usually in the range of  $500 \times 10^9/l$ ; levels above  $1,000 \times 10^9/l$  have been documented<sup>528</sup> but these are rare. The contributory importance of acute bleeding in such patients remains controversial.<sup>533,558</sup> The platelets return to normal levels following specific therapy with iron.<sup>541</sup>

The association of thrombocytosis with various *neoplasms* has been recognized for many years. The magnitude of thrombocytosis appears to be unrelated to the presence or absence of metastases.<sup>545</sup> The highest platelet counts have been found in association with carcinomas of the breast and lung, and with Hodgkin's disease.<sup>558</sup> Thrombosis is a common complication in patients with cancer, but the etiologic significance of the thrombocytosis is uncertain because of the frequent coexistence of the "hypercoagulable" state (page 1237) and, in some patients chronic intravascular coagulation. In some patients with cancer or Hodgkin's disease, unexplained thrombocytosis may be an important clue to the presence of an occult neoplasm.<sup>530,531</sup>

Thrombocytosis is commonly associated with various acute and chronic *inflammatory* and *infectious processes* (Table 34-1). Experimental inflammation produces a similar thrombocytosis in animals,<sup>326,567</sup> but the mechanism by which this occurs remains obscure. Moderate thrombocytosis also is common in cirrhosis of the liver.<sup>558</sup> In various inflammatory disorders of the bowel<sup>564</sup> and in rheumatoid arthritis, thrombocytosis is a

frequent finding; it may provide a sensitive indicator of improvement or relapse in the basic disease.<sup>512</sup>

In many other chronic disorders, reactive thrombocytosis is a less consistent finding (Table 34-7), eg, various chronic renal diseases,<sup>558</sup> glycogen storage disease.<sup>510</sup>

## Qualitative Disorders of Platelet Function

- Hereditary Disorders of Platelet Function
  - Thrombasthenia
  - Deficient Release Reaction
  - "Thrombopathy" (Deficient PF-3 Activity)
- Hereditary Platelet Dysfunction with Thrombocytopenia
- Miscellaneous Hereditary Forms
- Acquired Disorders of Platelet Function
  - Drug-Induced Platelet Dysfunction
  - Uremia
  - Platelet Dysfunction in Disorders of the Hematopoietic System
  - Effects of Fibrinogen Degradation Products on Platelet Function
  - Miscellaneous

DISORDERS of platelet function are difficult to classify because of the rarity of many forms, the numerous incompletely studied cases, and the considerable nosologic confusion which still surrounds this field. In the classification presented in Table 35-1, hereditary disorders are divided into three groups; namely, those in which platelet dysfunction is the sole abnormality (primary or "pure" forms); those in which mild to moderate thrombocytopenia is associated with abnormalities of platelet function; and a miscellaneous group, in which qualitative platelet dysfunction is but one facet of heritable disorders involving diverse organ systems. Platelet dysfunction also may complicate a wide variety of acquired disorders, but is seldom the sole abnormality. The discussion to follow will emphasize disorders in which abnormal platelet function appears to

be a major cause of bleeding. Information concerning disordered platelet function has accumulated at an unprecedented rate in the past decade and has been comprehensively reviewed.<sup>50,58,70,93,97,98,108</sup>

### Hereditary Disorders of Platelet Function

#### Thrombasthenia

It is now generally agreed that the term "thrombasthenia" (Glanzmann's thrombasthenia or disease, Glanzmann-Naegeli's disease, diacyclothrombopathia<sup>127</sup>) should be restricted to cases characterized by deficient ADP-induced platelet aggregation and deficient clot retraction.<sup>58,62</sup> Only when such diagnostic criteria are employed does this disorder emerge as a clearcut entity.

#### Pathophysiology

In thrombasthenia, the adhesion of platelets to collagen and the release reaction are normal, but the subsequent aggregation phase is lacking. Thrombasthenic platelets are refractory to the aggregating effects of ADP of either exogenous or endogenous origin (Fig. 35-1). This abnormality leads to a hemostatically inadequate platelet thrombus which presumably is the central feature in the pathogenesis of bleeding. Deficient platelet aggregation also may result in deficient plate-

**Table 35-1. Classification of the Qualitative Disorders of Platelet Function**

<b>I HEREDITARY</b>	
1	<i>Primary forms</i>
A	Thrombasthenia
B	Deficient release reaction
C	Thrombopathy* (deficient PF-3 activity)
2	<i>Varieties with thrombocytopenia</i>
A	The Bernard-Soulier syndrome
B	Thrombopathic thrombocytopenia
C	The Wiskott Aldrich syndrome
3	<i>Miscellaneous</i>
A	Hereditary afibrinogenemia
B	Heritable disorders of connective tissue
C	Other (mucopolysaccharidoses albinism glycogen storage disease)
<b>II ACQUIRED</b>

have been found in many other cases. In vitro,  $Mg^{++}$  partially corrects the deficient clot retraction in some cases, but this cation is present in normal amounts in the plasma and platelets of patients with thrombasthenia.<sup>16,20</sup>

More recently, a deficiency of glutathione peroxidase was demonstrated in the platelets of three patients with thrombasthenia.<sup>63</sup> This abnormality was associated with elevated levels of reduced glutathione in two of the three patients. Deficiency of platelet glutathione reductase has been reported in an unrelated kindred with this disorder.<sup>107</sup> These observations suggest that the ability of thrombasthenic platelets to withstand "oxidative" stress is deficient. The relationship between these metabolic abnormalities and the pathophysiology of thrombasthenia has not as yet been clarified.

There is good evidence for a general defect in the platelet membrane in this disorder.<sup>18</sup> Thus, washed thrombasthenic platelets are unable to adsorb various cationic proteins, including factor XIIa, IgG and IgM immunoglobulins, and fibrinogen.<sup>3</sup> Subnormal levels of both membrane-adsorbed fibrinogen and that which is intrinsic to the platelet organelles have been demonstrated in several cases.<sup>33,109,110,164</sup> This protein appears to be an important cofactor for ADP-induced platelet aggregation (page 391), and may be involved in platelet adhesion to fibrin, a phenomenon essential for clot retraction (page 398). However, normal amounts of platelet fibrinogen have been documented in some patients with severe aggregation abnormalities,<sup>22,29</sup> and the failure of affected platelets to adhere to fibrin<sup>20,95</sup> has not been consistently observed.<sup>18</sup> Thrombasthenic platelets produce subnormal activation of factor XIII<sup>30,164</sup> and possibly plasminogen as well.<sup>18,158</sup> Deficiencies of an unidentified membrane antigen have been demonstrated in two patients with thrombasthenia.<sup>110</sup> These observations provide additional evidence that the membrane of thrombasthenic platelets is abnormal, but electron microscopy has revealed only variable and probably nonspecific ultrastructural abnormalities.<sup>18,21,23</sup>

let factor 3 (PF-3) availability and impaired orientation of platelets with respect to fibrin strands. The latter abnormality may underlie deficient clot retraction.<sup>62</sup>

Numerous studies of platelet enzymes and biochemical pathways that provide energy for platelet functions have revealed no consistent abnormalities.<sup>18,22,172</sup> Deficiencies of platelet glyceraldehyde phosphate dehydrogenase and pyruvate kinase were demonstrated in one study,<sup>52</sup> but normal levels of these enzymes

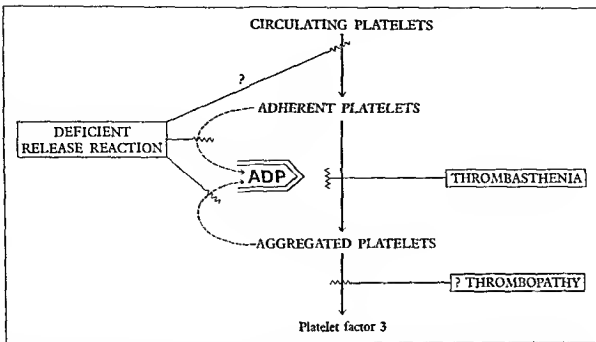

Fig 35-1. The pathophysiology of common disorders of platelet function. The sites of impairment of the processes of platelet adhesion and aggregation (solid arrows) and the release reaction (dashed arrows) in the various disorders (blocks) are indicated.

Although the platelet content of thrombosthenin is approximately normal as judged by qualitative techniques,<sup>62, 110, 172</sup> a deficiency of membrane-associated thrombosthenin (thrombosthenin S) has been demonstrated in the platelets of two patients with thrombasthenia by means of an immunohistochemical antibody staining method.<sup>11</sup> Other data suggest the presence of a qualitative abnormality of thrombosthenin.<sup>18a, 25</sup> In view of the hypothesized importance of this protein in both platelet aggregation and clot retraction (page 398), these observations, if confirmed, may provide a unifying concept of the pathophysiology of this disorder. However, it is probable that all cases presently included in this category are not the same,<sup>22</sup> and that a single molecular defect does not underlie all of the abnormalities which have been described.

### Clinical Features

More than 100 cases of thrombasthenia have now been reported. The disorder is inherited as an autosomal recessive trait and consanguinity is commonly present in

affected kindreds.<sup>118</sup> The disorder is clinically manifested by bleeding of the purpuric type. Common manifestations include epistaxis, menorrhagia, and gingival bleeding. Generalized ecchymoses may be striking.<sup>58</sup> In contrast to most other disorders of platelet function, spontaneous bleeding may be disabling, and post-traumatic and postoperative hemorrhage may be serious.

Heterozygotes are asymptomatic and laboratory studies usually show no abnormality, although deficient clot retraction as an isolated abnormality may be noted in some of these individuals.

### Laboratory Findings

The laboratory features of this disorder are summarized in Table 35-2. A prolonged bleeding time, deficient clot retraction, and the lack of ADP-induced platelet aggregation are characteristic and constant findings. Platelet aggregation by collagen, epinephrine, and other agents that act by releasing platelet-contained ADP is likewise deficient. The platelets are present in normal numbers

Table 35-2. Laboratory Findings in Disorders of Platelet Function

Test	Thrombasthenia	Deficient Release Reaction		Bernard-Soulier Syndrome
		Storage Pool Disease	Abnormal Release Mechanism	
Platelet count	U normal	U normal	U normal	Mild to moderate thrombocytopenia
Platelet morphology	Normal <sup>a</sup>	Normal microcytic <sup>c</sup> in some cases	—	Characteristic giant platelets
Bleeding time	M prolonged	V abnormality	U prolonged	U prolonged
Clot retraction	Deficient	Normal	Normal	Normal
Prothrombin consumption <sup>a</sup>	V abnormality	V abnormality	U abnormal	Abnormal <sup>g</sup>
Specific tests of PF-3 activity <sup>a</sup>	Abnormal <sup>†</sup>	V abnormality <sup>ab</sup>	V abnormality	V abnormality
Platelet retention in glass bead columns (glass "adhesion")	Reduced <sup>†</sup>	Reduced <sup>†</sup>	Reduced	—
Platelet aggregation by 5 $\mu$ M ADP	Deficient	Normal	Normal	Normal <sup>a</sup>
Platelet aggregation by "threshold" concentrations of ADP (0.2–1.5 $\mu$ M)	Deficient	V deficiency with subsequent disaggregation	V deficiency with subsequent disaggregation	Normal <sup>a</sup>
Platelet aggregation by dilute collagen suspensions and 5 $\mu$ M epinephrine	Deficient	Deficient <sup>†</sup>	Deficient	Normal <sup>a</sup>
Platelet aggregation by bovine fibrinogen (1.5 mg/ml)	V abnormality	Normal	Normal	Deficient
Storage nucleotide pool	Normal	Diminished	Normal	Normal <sup>h</sup>
Ancillary laboratory features	<sup>a</sup> Platelets appear discrete and rounded in stained smears <sup>†</sup> Not corrected by ADP Serum defects in TGT Platelet fibrinogen commonly decreased	<sup>c</sup> Corrected by ADP <sup>†</sup> Second wave of epinephrine-induced aggregation absent or markedly reduced Platelet dense bodies reduced in number	In vitro effects of aspirin are additive	Initial shape change lacking <sup>g</sup> One-stage techniques <sup>a</sup> Aggregation may be abnormally rapid <sup>h</sup> Corrected for increased platelet volume Ristocetin-induced platelet aggregation deficient

\*Results vary depending on exact technique employed  
Key: U = usually, M = markedly, V = variable

and are morphologically normal when viewed by light microscopy. In stained blood smears, however, the platelets remain discrete, round, and "isolated" as a result of deficient adhesion and aggregation,<sup>18,62</sup> which may explain reports of morphologic abnormalities. Clot retraction usually is absent, but may be detectable in an occasional subject.<sup>18</sup> Abnormalities in prothrombin consumption are variable, but the results of more sensitive tests of PF-3 activity usually are abnormal.<sup>158</sup> Correction is not obtained by the addition of exogenous ADP. Contact activation is subnormal in serum prepared from the blood of thrombasthenic patients,<sup>158</sup> and as a consequence the serum functions abnormally in the thromboplastin generation test (TGT). This has led to an erroneous diagnosis of factor IX deficiency in several cases. The results of other tests of coagulation are normal. Thromboelastographic tracings resemble those obtained in severe thrombocytopenia.<sup>18</sup>

### Treatment

There is no specific treatment. Corticosteroids and other nonspecific measures have been tried without effect. The transfusion of fresh blood or platelet concentrates has been beneficial in some patients<sup>171</sup> and disappointing in others.<sup>62</sup>

### Deficient Release Reaction

This disorder is the result of the inability of affected platelets to undergo a normal release reaction when physiologically stimulated. It is also known as "storage pool disease,"<sup>162</sup> the *Portsmouth syndrome*,<sup>114</sup> *primary platelet dysfunction*,<sup>181</sup> and "thrombopathia," the last in somewhat confusing contradistinction to "thrombopathy" or "thrombocytopenia"—disorders to be discussed below—in which deficient PF-3 activity is assumed to be the major abnormality. Similar but not identical defects in the release reaction apparently underlie platelet dysfunction which complicates a wide variety of acquired diseases, and that which is produced by numerous commonly used drugs.

### Pathophysiology

In this disorder, the platelets aggregate normally in response to exogenous ADP, but fail to release normal amounts of endogenous ADP (Fig. 35-1). As a consequence, the initial steps in platelet aggregation are not "re-enforced" or "amplified" by the release reaction and the resulting secondary wave of aggregation. The latter process apparently is essential for the rapid formation of a stable platelet plug (page 394).

In most cases, the basic defect appears to be a deficiency of storage nucleotides in affected platelets. Thus, Holmsen and Weiss<sup>72,73</sup> demonstrated an abnormally high specific activity of ATP and ADP in affected platelets isotopically labeled by incubation with <sup>14</sup>C-adenine. The conversion of labeled ATP into inosine monophosphate (IMP) and hypoxanthine proceeded normally. Similar abnormalities can be produced in normal platelets if their storage nucleotides are depleted by treatment with collagen. These data have been confirmed by others,<sup>59</sup> and suggest that in this disorder, which has been termed "storage pool disease," deficient ADP release is due to deficiency of available storage ADP and not to abnormalities in the pathways that supply energy to the release mechanism.<sup>73,163</sup> In other cases,<sup>73,162,165</sup> the storage nucleotide pool was normal, suggesting that the abnormalities in the release reaction were due to a different defect, which resembles that produced by aspirin. It is probable that several different biochemical abnormalities underlie hereditary deficiency of the release reaction.<sup>72,116</sup>

Deficiency of ADP release may be quantitated,<sup>63,160</sup> and in vitro gives rise to deficient platelet aggregation by agents that act by promoting the release of platelet ADP, eg, collagen, epinephrine, thrombin. Although deficient ADP release appears to be central to the pathogenesis of the bleeding, the uptake, storage, and release of substances other than ADP which are normally contained within the platelet also are subnormal, eg, serotonin, epinephrine, PF-4.<sup>57,73</sup>

Electron microscopy has revealed sub-

normal numbers of platelet "dense bodies" (Fig. 9-1, page 374) in the platelets of several patients with this disorder,<sup>59,162</sup> an observation which is consistent with the fact that this organelle is the major storage site for both ADP and serotonin. An identical abnormality is also present in albinism,<sup>162,169</sup> and may represent a truly specific ultrastructural manifestation of "storage pool disease."<sup>169</sup>

### Incidence and Clinical Features

The incidence of hereditary deficiency of the release reaction is unknown. If cases previously classified as "thrombopathy" are found to represent defects of the release reaction, as discussed below, the disorder would be relatively common.<sup>50</sup> The disorder appeared to be inherited as an autosomal dominant trait in several kindreds.<sup>22,23,100,168</sup> In others, a lifelong hemorrhagic diathesis was present but family members were unaffected.<sup>61,121</sup> Hereditary platelet dysfunction presumably due to deficiency of storage ADP also has been described in rats.<sup>154</sup>

The clinical picture is usually one of mucocutaneous bleeding of mild to moderate severity. Hematuria and epistaxis are common, but post-traumatic bleeding is seldom severe. Petechiae are relatively uncommon, and in many patients the only complaint was easy bruising.

### Laboratory Findings

The usual laboratory findings are summarized in Table 35-2. The bleeding time usually is moderately prolonged, but varies from normal<sup>100</sup> to markedly prolonged,<sup>22</sup> and fluctuates from time to time in the same patient.<sup>131</sup> The platelet count and results of coagulation studies are normal, clot retraction is normal. In several affected families the platelets were significantly smaller than normal.<sup>100,168</sup> The megakaryocytes are present in normal numbers and their morphologic appearance also is normal. Abnormalities of PF-3 activity have been demonstrated in most subjects, but are not invariably present.<sup>116,131</sup>

Platelet aggregation by high concentrations of exogenous ADP (5  $\mu$ M or higher) is normal. However, the amount of ADP required to produce the release of platelet-contained ADP and a "secondary" wave of aggregation ("threshold" concentration) has been found in this disorder to be two to three times higher than normal.<sup>63</sup> Consequently, concentrations of ADP that normally would suffice to induce optimal and irreversible aggregation (0.2 to 1.5  $\mu$ M) may produce slightly subnormal aggregation<sup>58</sup> that is rapidly followed by spontaneous deaggregation (Fig. 35-2).<sup>58,61,63,131</sup> Aggregation by collagen and epinephrine is deficient, and with the latter agent the second part of the normally biphasic aggregation curve is lacking (Fig. 35-2). Abnormalities in collagen-induced aggregation have been documented in apparently normal persons,<sup>150</sup> and may be minimized or abolished if concentrated collagen suspensions are used.<sup>111,131</sup> Serious diagnostic confusion may result from ingestion of aspirin or related drugs, which produce similar laboratory abnormalities.

### Treatment

There is no specific treatment for this disorder. The efficacy of platelet transfusions has not been adequately studied.<sup>131</sup>

### "Thrombopathy"

The term "thrombopathy" is usually employed in the sense proposed by Braunsteiner and Pakesch<sup>17</sup> to refer to platelet dysfunction manifested by defective coagulant activity of the platelets, i.e., deficient PF-3 activity (Fig. 35-1). Bowie and Owen<sup>14</sup> have divided these disorders into "deficit" thrombopathies, disorders in which PF-3 content of platelets is subnormal, and "functional" thrombopathies wherein the "availability" or "release" of PF-3 is deficient, although the total content is normal. Hereditary and acquired forms have been described in both categories. Other variants,<sup>16</sup> and "compound" defects, representing combinations of thrombopathy,

Fig. 35-2. Aggregometer tracings in a patient with deficient release reaction. Aggregating agents were added at zero time. Note the disaggregation observed with low ADP concentrations (B), the absence of the secondary wave of epinephrine-induced aggregation (C), and the absence of collagen-induced aggregation (D). The patient was a 31 year old man with partial albinism. Ancillary findings included characteristic pigmented reticulum cells in the bone marrow, and abnormally small platelets.

thrombasthenia, and deficiencies of factors VIII<sup>36</sup> and IX, also have been described.<sup>14</sup>

Bleeding manifestations are mild, and serious hemorrhage is rare. In addition to abnormal prothrombin consumption and deficient PF-3 activity of the platelets in various *in vitro* systems, the bleeding time may be prolonged but often is normal. Clot retraction is normal. There is no specific treatment of established value, although corticosteroids have produced improvement in some cases.

The status of "thrombopathy" as a specific form of platelet dysfunction may now be questioned.<sup>50,70,97</sup> The mechanism by which deficient PF-3 activity alone leads to a prolonged bleeding time and clinical bleeding remains unclear. *In vitro* studies by Hardisty

and Hutton<sup>60</sup> and others<sup>2,160</sup> have established that PF-3 activity normally is proportional to and dependent upon platelet aggregation in earlier steps. A large number of drugs that alter the platelet release reaction also produce abnormalities in PF-3 activity,<sup>108</sup> and studies of many of the acquired forms of platelet dysfunction previously termed "thrombopathy" have revealed clearcut abnormalities in platelet aggregation, eg, in uremia, myelofibrosis. "Thrombopathy" would thus appear to be closely related to if not identical with deficient release reaction.<sup>60,70,160</sup> The entire subject has been confused by the previously discussed inadequacies in terminology and in available methods for measurement of "platelet factor 3"<sup>97,98</sup> (page 397).

### Hereditary Platelet Dysfunction with Thrombocytopenia

#### Bernard-Soulier Syndrome

The Bernard-Soulier syndrome is a relatively rare disorder that was first described in 1948 under the name "*dystrophie thrombocytaire hémorragique congénitale*."<sup>7</sup> It is characterized by giant platelets, mild thrombocytopenia, bleeding out of proportion to the reduction in platelet numbers, and variable abnormalities in PF-3 activity. The disorder is inherited as an autosomal recessive trait, and consanguinity is common in reported kindreds.<sup>7,93</sup> Heterozygotes are almost invariably asymptomatic, but, in some, mild deficiency of PF-3 activity and "giant" platelets are present. The clinical picture is one of moderate to severe bleeding manifestations of the purpuric type, including bruising, epistaxis, and menorrhagia. There is no known therapy, and splenectomy has been ineffective.

The morphologic abnormalities of the platelets are the most consistent and striking feature of the disorder (Fig. 35-3). The platelets range in size up to  $8\ \mu\text{m}$  in diameter,

have a relatively dense granulomere, and have been described as "lymphocytoid."<sup>93</sup> The megakaryocytes are normal or increased in number, but reveal no characteristic morphologic abnormalities.

The nature of platelet dysfunction in this disorder has not been well characterized. The bleeding time is prolonged, but clot retraction, and platelet aggregation by ADP and collagen are normal.<sup>8,53,93</sup> Platelet aggregation by bovine fibrinogen<sup>8,46a</sup> and by Ristocetin<sup>41,96</sup> is deficient.<sup>8</sup> In two cases, the initial shape change normally produced by ADP was not evident.<sup>8</sup>

Grøttum and Solum<sup>53</sup> demonstrated reduced electrophoretic mobility of affected platelets, which they attributed to deficiency of sialic acid in the membrane. These observations may explain the "hyperaggregability" of giant platelets which has been frequently observed.<sup>8,93</sup> No other abnormalities in platelet biochemistry or characteristic ultrastructural features have been described.<sup>112</sup> In two reports,<sup>37,53</sup> biphasic platelet survival curves suggested the presence of two populations of platelets, i.e., the "giant" forms which survived only 0.5 to 0.6 day, and smaller platelets which had a normal survival time.

## "Thrombopathic" Thrombocytopenia

"Thrombopathic" thrombocytopenia is a disorder that resembles the Bernard-Soulier syndrome in most respects, but is inherited as an autosomal dominant trait<sup>69,89,92,123</sup> Platelet counts of 20,000 to 80,000/ $\mu$ l with numerous "giant" forms have been reported, in spite of normal numbers and normal morphologic appearance of the megakaryocytes.<sup>89</sup> In one kindred<sup>92</sup> the morphologic abnormalities of the platelets antedated the thrombocytopenia, and bleeding ameliorated at the time of adolescence. Subtle variations in the appearance of the abnormal platelets have been noted,<sup>92</sup> and ultrastructural studies have revealed a reduced number of alpha granules.<sup>89,157</sup> In one kindred,<sup>3</sup> the total nucleotide content of the "giant" platelets was normal when results were corrected for platelet volume, but other studies demonstrating deficient collagen-induced aggregation and PF-3 activity suggested an abnormality of the release reaction.

Giant platelets and moderate thrombocytopenia apparently are common in certain populations of Mediterranean extraction.<sup>91</sup> They may be associated with other hereditary or congenital syndromes, eg, monoclonal gammopathy,<sup>183</sup> autosomal dominant nephritis and deafness.<sup>43</sup>

## Wiskott-Aldrich Syndrome

In addition to thrombocytopenia and specific abnormalities of immunologic defense, the Wiskott-Aldrich syndrome (Chapter 44) is characterized by qualitative abnormalities of platelet function. Platelets from affected persons are smaller than normal and, under the electron microscope, reveal deficiencies in the number of alpha granules and other ultrastructural abnormalities.<sup>54</sup> Platelet aggregation induced by epinephrine, ADP, and collagen is deficient, and the platelet storage pool of adenine nucleotides is subnormal. Studies by Kuramoto et al<sup>88</sup> demonstrated an interesting metabolic defect in the platelets in persons with this disorder. The abnormality

was manifested by deficient CO<sub>2</sub> production in the citric acid cycle following exposure of platelets to latex particles and aggregating agents. Kuramoto and associates suggested that a similar defect in the metabolic response of macrophages could underlie abnormalities in antigen processing. The major discussion of this syndrome will be found on page 1387.

Minor abnormalities in PF-3 activity have been reported in some cases of the *May-Hegglin anomaly*<sup>86</sup> (page 1322).

## Miscellaneous Hereditary Forms

### Hereditary Afibrinogenemia

In contrast to most coagulation disorders, hereditary afibrinogenemia (Chapter 37) is usually associated with a prolonged bleeding time. As discussed elsewhere (page 392), fibrinogen apparently is required for ADP-induced platelet aggregation, and severe deficiencies of this factor produce a secondary abnormality in platelet function manifested *in vitro* by deficient platelet aggregation with low concentrations of ADP,<sup>140</sup> markedly defective adhesiveness of platelets to glass,<sup>166</sup> and variable abnormalities in PF-3 activity.<sup>55,78</sup> All of these abnormalities are corrected by fibrinogen both *in vivo* and *in vitro*. Defective hemostasis in this disorder may also result from a lack of the stabilizing effect of fibrin on the platelet thrombus.<sup>128</sup>

### Heritable Disorders of Connective Tissue and Mucopolysaccharidoses

Abnormally large platelets and laboratory data suggesting abnormalities in ADP release have been described in patients with various heritable disorders of connective tissue, including the Marfan syndrome, osteogenesis imperfecta,<sup>67</sup> and the Ehlers-Danlos syndrome<sup>44,45,84</sup> and in those with mucopolysaccharidoses. Many of these patients had no history of abnormal bleeding, and in others the results of platelet function studies were normal despite the presence of large platelets.

Various coagulation abnormalities may be associated with these disorders,<sup>45</sup> and bleeding may also result from defective vascular support (Chapter 38). Platelets do not adhere normally to collagen obtained from patients with the Ehlers-Danlos syndrome.<sup>62a</sup>

### Albinism

A mild to moderate hemorrhagic disorder associated with prolongation of the bleeding time has been reported in several patients with albinism. In some, abnormal ceroid-like pigmentation of the leukocytes<sup>169a</sup> and reticulum cells of the bone marrow was observed (Hermansky-Pudlak syndrome).<sup>68,154</sup> In adequately studied cases, deficient storage of ADP, reduced numbers of platelet "dense bodies,"<sup>102,160</sup> and platelet function abnormalities characteristic of deficient ADP release were found<sup>58,59,93</sup> (Fig. 35-2).

### Glycogen Storage Disease

A mild bleeding diathesis with prolonged bleeding time, deficient PF-3 activity, and abnormalities of platelet aggregation compatible with defective ADP release has been reported in patients with glycogen storage disease.<sup>37a,49,66,113a</sup> Platelet dysfunction was thought to be due to interaction of the platelets with factors in the plasma, possibly lipids.

### Unclassified Varieties

As is the case with the hereditary coagulation disorders, a large literature has accumulated concerning isolated kindreds or single case reports that appear to represent unique disorders of platelet function. Under the name "gray platelet syndrome", Raccuglia<sup>126</sup> described a disorder manifested by lifelong purpura. The patient initially presented with moderate thrombocytopenia, which was successfully treated by splenectomy. Prolongation of the bleeding time and poor clot retraction persisted despite normal platelet numbers. The platelets revealed an almost total lack of granules, and a peculiar gray

color in Wright-stained blood smears. Biochemical studies of affected platelets demonstrated moderate reduction in platelet ATP and in extractable phosphatides, but aggregation with ADP, epinephrine and collagen, and PF-3 activity as measured in the TGT were normal. Family studies failed to provide evidence for a hereditary origin.

Many other reports appear to represent minor variants of the more common forms already discussed. Thus, "essential athrombia"<sup>77,142</sup> refers to a disorder that resembles thrombasthenia in all respects, except for the presence of detectable clot retraction. A structural defect in collagen obtained from one patient appeared to underlie deficient platelet adhesion to collagen fibers.<sup>19</sup> Adhesion to collagen was deficient in several other patients affected with a disorder which resembled deficient release reaction in most other respects.<sup>22,71,116,131</sup> Quite similar cases have also been reported as "mild" thrombasthenia.<sup>34</sup> Whether or not these cases represent unique variants is unclear. Numerous reports of "hybrid" forms of platelet dysfunction and of genetic variants of well-recognized forms are not entirely convincing.<sup>120,121,122,130,134,137,145</sup>

## Acquired Disorders of Platelet Function

### Drug-Induced Platelet Dysfunction

A great many chemically and biologically active substances can be shown to inhibit platelet function, and much basic information has been obtained from the study of the *in vitro* effects of agents such as structural analogs of ADP and supraphysiologic concentrations of various drugs.<sup>108</sup> These data are briefly discussed in Chapter 9. The present discussion will be limited to drugs in common use which impair platelet function in therapeutic concentrations. Such drugs are listed in Table 35-1. The rapidly expanding body of knowledge concerning the influence of drugs on platelet function has been reviewed.<sup>70,97,104,108</sup>

## Mechanism of Action

In ordinary therapeutic doses aspirin will impair the platelet release reaction and secondary platelet aggregation for approximately one week.<sup>16,161,167,168</sup> This has been attributed to the irreversible acetylation of membrane proteins.<sup>1</sup> A similar mechanism cannot explain the action of the pyrazole compounds, since their effects are readily reversible and depend on continuously maintained blood levels.<sup>108</sup> Aspirin does not affect the storage nucleotide pool, but has been shown to impair glucose uptake, lactate production, and the transformation of ATP to IMP and hypoxanthine. These findings indicate an impairment of the pathways involved in the production or transfer of energy required in the release reaction.<sup>4,40</sup> Aspirin<sup>111</sup> and indomethacin<sup>118</sup> inhibit the production of prostaglandin  $E_2$  by platelets, an effect which may underlie the inhibition of the release reaction produced by these anti-inflammatory agents.<sup>16,99</sup> The antidepressants and some antihistamines are thought to "stabilize" mitochondria and biologic membranes,<sup>108</sup> whereas alpha-adrenergic blocking agents prevent the facilitation of ADP-induced aggregation by various sympathomimetic amines<sup>108</sup> (page 1102). The methyl xanthines act by inhibiting platelet phosphodiesterase, which leads to an increase in platelet levels of cAMP (Fig. 9-8, page 395). Dextran and related polymers presumably act by coating the platelets and altering the surface change.<sup>159</sup> Glyceryl guaiacolate is a structural analog of adenosine and inhibits ADP-induced platelet aggregation<sup>139</sup>; many other drugs produce similar effects in supraphysiologic concentrations.<sup>104,108</sup> Ethanol inhibits both primary and secondary ADP-induced aggregation.<sup>67a</sup> Most of the drugs included in Table 35-1 produce vasodilatation,<sup>99</sup> thus suggesting that they act on the contractile apparatus of the platelet.<sup>97</sup>

## Significance of Drug-Induced Platelet Dysfunction

The abnormalities produced by the drugs listed in Table 35-1 are quite variable, but

resemble in most respects those associated with hereditary deficiency of the release reaction as described above (Table 35-2). The bleeding time may be slightly prolonged, but often is not above the limits of normal. The results of more sensitive tests such as collagen and epinephrine-induced platelet aggregation may be abnormal and thus may lead to serious diagnostic confusion.

In otherwise normal persons, the impairment of platelet function produced by drugs is usually of no clinical significance, although a mild purpuric disorder may be observed in association with chronic aspirin ingestion. To the contrary, in patients with hereditary coagulation disorders, in uremic patients, and in patients receiving heparin or coumarin anticoagulants, impairment of platelet function by drugs may remove one of the remaining hemostatic defenses and result in serious bleeding.<sup>81</sup> In pregnant women, aspirin may cross the placenta and produce significant impairment of platelet function in the fetus.<sup>9</sup> Analgesics which are presumably safe in these patients include acetaminophen and propoxyphene.<sup>50</sup> Of perhaps greater long-term significance is the possible usefulness of drugs that impair platelet functions in the treatment and prevention of thrombosis (Chapter 39).<sup>97,108,161</sup>

## Uremia

Although the hemostatic defect in uremia often is complex and may include thrombocytopenia (page 1102) and minor coagulation abnormalities, it is probable that platelet dysfunction is the most consistent and clinically important feature.<sup>97</sup> Uremia was one of the first "acquired thrombopathies" to be described. The basic defect appears to be in the release reaction. Thus, deficient collagen<sup>125</sup> and epinephrine-induced aggregation,<sup>74</sup> impaired glass "adhesiveness,"<sup>42,132</sup> and a lack of the secondary wave of ADP-induced aggregation and subsequent disaggregation<sup>76</sup> have been demonstrated in several studies. The bleeding time is variably prolonged and prothrombin consumption and PF-3 activity usually are deficient.

There is ample evidence that these abnormalities are produced by a dialyzable factor in the plasma, but the nature of the responsible substance remains controversial.<sup>147,156</sup> In vitro, the effects of creatinine are variable and inconsistent, but urea,<sup>38a</sup> guanidosuccinic acid,<sup>74,75</sup> a metabolite of urea, and various phenols and phenolic acids<sup>124,125</sup> produce many of the characteristic laboratory abnormalities. Hypermagnesemia, which is present in many uremics, may be involved.<sup>38</sup> It is probable that numerous metabolites that accumulate in the plasma in uremia may separately or collectively affect platelet function.

Bleeding may be severe in the uremic patient. Widespread ecchymoses and intractable slow gastrointestinal bleeding are common, and large hemorrhages into serous cavities and into muscles may occur. Hemodialysis and peritoneal dialysis are of temporary therapeutic value. It should be pointed out that uremia is frequently a complicating factor in other complex hemorrhagic disorders, eg, multiple myeloma, severe liver disease, chronic forms of intravascular coagulation.

### Platelet Dysfunction in Disorders of the Hematopoietic System

#### The Paraproteinemias

The bleeding diathesis which may complicate the various paraproteinemias (Chapter 53) is exceedingly complicated. Factors that may play a role either alone or in combination include thrombocytopenia, fibrinolysis, various coagulation abnormalities, including those caused by specific and nonspecific inhibitors, vascular infiltration, and uremia.<sup>117</sup>

Platelet dysfunction can frequently be demonstrated, and is most common in macroglobulinemia.<sup>105,115</sup> Deficient PF-3 activity, reduced platelet adhesiveness,<sup>117</sup> and variable abnormalities of aggregation<sup>140</sup> have been documented and have been attributed to coating of the platelet membrane with abnormal protein.<sup>115</sup> In contrast to normal immunoglobulins, purified IgG fractions from patients with multiple myeloma, and IgM fractions from patients with macroglobulinemia, do not restore the aggregability

of washed normal platelets.<sup>5</sup> The displacement of normal proteins from the plasmatic atmosphere by aberrant proteins of various types may explain the aggregation abnormalities.

The presence of marked hyperglobulinemia may produce unique in vitro abnormalities. Thus, in one patient with multiple myeloma, deficient clot retraction not attributable to either thrombocytopenia or platelet dysfunction resulted from coating of fibrin strands by abnormal plasma proteins.<sup>90</sup> A similar interaction between abnormal proteins and collagen fibers was the apparent cause of abnormal platelet function in another patient.<sup>155</sup> The latter phenomenon may significantly impair hemostasis in vivo, since the bleeding time in these disorders often is normalized by plasmapheresis.<sup>51</sup>

#### Hemorrhagic Thrombocythemia, Myelofibrosis, and Polycythemia Vera

Bleeding has long been recognized as a complication of these disorders.<sup>56</sup> Common bleeding manifestations include ecchymoses, epistaxis, gastrointestinal bleeding, and a propensity to serious hemorrhage following minor trauma or surgical procedures. Petechiae are uncommon.

Hemorrhagic ("idiopathic") thrombocythemia (Chapter 34) is characterized by marked elevations of the platelet count, the magnitude of which appears to be correlated with the prolongation of the bleeding time and the severity of hemorrhage.<sup>103</sup> Large and morphologically abnormal platelets may be seen in stained smears, and deficiencies of PF-3 activity<sup>149,163</sup> and diminished platelet retention<sup>35</sup> have been reported. In contrast, none of these abnormalities was found in "reactive" or "secondary" thrombocytosis, conditions in which bleeding is uncommon.<sup>103</sup> However, platelet content and uptake of serotonin were reported to be subnormal both in patients with hemorrhagic thrombocythemia and in those with "secondary" thrombocytosis following splenectomy.<sup>103</sup>

In some cases,<sup>143</sup> a curious constellation of abnormalities was described which included normal PF-3 activity despite deficient

ADP-induced aggregation, and normal collagen-induced aggregation together with markedly diminished epinephrine-induced aggregation. In others, data consistent with a deficient release reaction have been obtained.<sup>148</sup> The inhibitory effects of high platelet concentrations in the TGT<sup>143</sup> and the inconstant and minor coagulation abnormalities that have been reported<sup>17,135</sup> are of doubtful pathophysiologic significance.

In myelofibrosis (Chapter 57), numerous reports of "thrombopathy"<sup>39,162</sup> have substantiated the presence of deficient PF-3 activity; an abnormality that may be present even in the absence of thrombocytosis.<sup>39</sup> Similar observations have been reported in polycythemia vera,<sup>79,82,163</sup> and preliminary evidence suggests that the release reaction is abnormal in this disorder.<sup>27</sup> The abnormalities in clot retraction, the phenomenon of "red cell fallout" and the "fragile" clots that have been described in polycythemia vera may be artifacts resulting from the markedly increased red cell mass.<sup>136</sup> In chronic myelocytic leukemia, an abnormal substance in the plasma, possibly an adenosine deaminase, produces abnormalities in platelet function.<sup>117a</sup>

The clinical importance of platelet dysfunction in hemorrhagic thrombocytopenia, myelofibrosis, polycythemia vera and chronic myelocytic leukemia remains unclear. Thromboembolic complications are common. The role of platelets and functional abnormalities thereof in the pathogenesis of thrombosis is currently under intensive study<sup>97,108,161</sup> (Chapter 39). Therapy directed at the underlying disorder may produce a parallel improvement in the bleeding and thromboembolic manifestations. Platelet transfusions have been helpful in some cases.<sup>27</sup> The treatment of thrombocytosis is discussed on page 1106.

#### Effects of Fibrinogen Degradation Products on Platelet Function

Fibrinogen degradation products (FDP) are protein fragments that result from the proteolytic cleavage of fibrin or fibrinogen by plasmin (Fig. 10-8, page 437). In vitro, FDP

in relatively high concentrations impair both ADP-induced aggregation and the release reaction.<sup>6,85</sup> In some studies, the large fragments X and Y ("early" FDP) appeared to be the more potent in this respect,<sup>80,85</sup> whereas in others much smaller dialyzable fragments were the more active.<sup>94,144,151</sup> It has been suggested that FDP are adsorbed to the platelet surface in competition with plasma fibrinogen, which is important as a cofactor of ADP.<sup>85</sup>

Impairment of platelet function has been correlated with in vivo levels of FDP in experimentally induced hyperfibrinolysis in dogs<sup>86</sup> and in man following therapeutic defibrination with Arvin.<sup>119</sup> The levels of FDP also parallel the severity of bleeding in many patients with cirrhosis of the liver.<sup>152</sup> In cirrhosis, inadequate hepatic clearance of plasminogen activators (page 1205) frequently results in persistent fibrinogenolysis and high levels of FDP. Impairment of platelet functions by FDP may thus be an important contributory cause of bleeding in fibrinogenolysis, disseminated intravascular coagulation, and decompensated liver disease (Chapter 38).

Fibrin monomers and complexes thereof<sup>108</sup> and polymerizing fibrin<sup>113</sup> also are often present in the plasma of cirrhotics, possibly as the result of low-grade intravascular coagulation.<sup>151</sup> In vitro, these derivatives accelerate ADP-induced platelet aggregation, and in vivo may lead to sequestration of platelets and thrombocytopenia (page 438). Thus, in decompensated liver disease, and possibly in intravascular coagulation as well, both the number and functional competence of the platelets may vary, depending on a continuously shifting balance between inhibitory and acceleratory effects of various fibrinogen derivatives.<sup>151</sup>

#### Miscellaneous

Platelet dysfunction has been reported in various other hematologic disorders<sup>26,98,129</sup> including idiopathic thrombocytopenic purpura,<sup>10,32</sup> acute and chronic leukemia,<sup>24,33a,48,163</sup> systemic lupus erythemato-

sus,<sup>163</sup> pernicious anemia,<sup>146</sup> and factor VIII deficiency.<sup>26,39</sup> In most cases, platelet dysfunction appeared to be a minor or inconsistent feature of the disorder.

Significant bleeding may occur in scurvy, and has traditionally been attributed to vascular abnormalities (Chapter 36). Significant platelet dysfunction has been reported in some cases of scurvy in man<sup>31,170</sup> and in scorbutic animals.<sup>12</sup> When performed, aggregation studies have suggested an abnormality in the release reaction.<sup>68</sup> Poorly defined abnormalities in platelet function also have been described in patients with congenital heart disease<sup>66,67,101</sup> and homocystinuria.<sup>173</sup>

knowledge of the basic pathophysiology remains fragmentary. Laboratory techniques for the study of vascular disorders are grossly inadequate, and the diagnosis usually is made from the appearance of the lesions and the clinical findings (Table 36-2), which fortunately often are characteristic. The results of laboratory tests of hemostasis and blood coagulation usually are within normal limits, and even painstaking pathologic study of biopsy material often reveals nonspecific findings. Although a wide variety of therapeutic agents has been tried, treatment remains purely empiric and usually is ineffective.

### **Autoimmune Vascular Purpuras**

#### **Allergic Purpura**

The term "allergic purpura" (anaphylactoid purpura, Henoch-Schönlein purpura) refers to a syndrome characterized by a relatively distinctive purpuric eruption in association with various constitutional and localized symptoms.<sup>1,28,41</sup> Such a broad clinical definition has proved useful, but encompasses a rather varied group of cases, and it is probable that the syndrome of allergic purpura represents one of the more benign clinical expressions of diffuse "autoimmune" vascular

**D**ISORDERS in which the major cause of bleeding is presumably an abnormality of the vessels or their supporting tissues are summarized in Table 36-1. Bleeding has often been attributed to such vascular disorders, primarily because no abnormalities of the platelets or of the coagulation mechanism could be demonstrated. A number of disorders previously consigned to this "diagnostic wastebasket" are now known to be associated with specific abnormalities of coagulation or platelet function, eg, uremia, hereditary deficiency of the release reaction, von Willebrand's disease. However, in the majority of the disorders to be discussed,

**Table 36-1. Purpuras Due Mainly to Vascular Abnormalities**

<b>I AUTOIMMUNE VASCULAR PURPURAS</b>	
1	The allergic purpuras
2	Drug induced vascular purpura (iodides, <sup>127</sup> belladonna, atropine quinine <sup>151</sup> procaine penicillin <sup>53</sup> phenacetin aspirin, <sup>122</sup> merbaphen, chloral hydrate and other sedatives, <sup>110</sup> various sulfonamides, coumarins others <sup>54</sup> )
3	Purpura fulminans (page 1219)
<b>II INFECTIONS</b>	
1	Bacterial (meningococcemia and septicemia due to other organisms <sup>144</sup> typhoid fever, scarlet fever <sup>23</sup> diphtheria tuberculosis <sup>20</sup> endocarditis <sup>145</sup> bacterial products <sup>125</sup> others)
2	Viral (smallpox influenza measles others)
3	Rickettsial (Rocky Mountain spotted fever typhus others)
4	Protozoal (malaria <sup>153</sup> )
<b>III STRUCTURAL MALFORMATIONS</b>	
1	Hereditary hemorrhagic telangiectasia
2	Hereditary disorders of connective tissue (Ehlers-Danlos syndrome osteogenesis imperfecta pseudoxanthoma elasticum)
3	Acquired disorders of connective tissues (scurvy corticosteroid purpura Cushing's disease, senile purpura, cachectic purpura)
<b>IV MISCELLANEOUS</b>	
1	Autoerythrocyte sensitization and related syndromes (DNA hypersensitivity cutaneous hyperactivity to hemoglobin psychogenic purpura, vicarious bleeding stigmata)
2	Paraproteinemias (page 1152) (hyperglobulinemic purpura cryoglobulinemic purpura Waldenström's macroglobulinemia, others)
3	Purpura simplex and related disorders (orthostatic and mechanical purpura, factitious purpura)
4	Purpura in association with certain skin diseases (annular telangiectatic purpura, angioma serpiginosum Schamberg's disease, pigmented purpuric fichenoid dermatitis)
5	Others (blood borne tumor emboli <sup>154</sup> snake venoms, <sup>132</sup> hemochromatosis <sup>155</sup> amyloidosis <sup>147</sup> other chronic diseases)

injury. A similar process presumably underlies a broad spectrum of poorly understood disorders including the inflammatory erythemas,<sup>142</sup> various collagen vascular disorders,<sup>42,142</sup> certain "immune complex" diseases,<sup>44</sup> and various forms of vasculitis<sup>42</sup> and allergic granulomatosis.<sup>142</sup>

## Etiology and Pathophysiology

The basic lesion is an inflammatory process, involving mainly the capillaries and arterioles, which results in perivascular infiltration and serosanguineous effusions into subcutaneous, submucous, and subserous tissues. Such effusions produce, in addition to purpura, the various localized and generalized manifestations. It is generally assumed that the disorder is the result of an autoimmune process, but the evidence for this is scanty and indirect. Similar lesions can be produced experimentally in rats by the sequential injection of agar and epinephrine,<sup>52</sup> and in dogs<sup>17</sup> and guinea pigs by administration of rabbit antisera against guinea pig vascular endothelium. Attempts to demonstrate a humoral antibody serologically have been unsuccessful, but in one patient in whom allergic purpura was associated with the administration of quinine, readministration of the offending drug produced transient thrombocytopenia, increased capillary fragility, and erythrophagocytosis.<sup>19</sup>

A few cases have been described in which hypersensitivity to certain foods seemed to be the cause of the disorder,<sup>4</sup> but in only a minority is the evidence convincing. Eggs, milk,<sup>35</sup> chocolate, wheat, and beans have been implicated most often.<sup>1,2,33</sup> Hypersensitivity to cold,<sup>46,49</sup> insect bites,<sup>14</sup> and rarely to drugs<sup>18,19,22</sup> also has been associated.

The frequency with which the onset of allergic purpura follows various infectious diseases has led to extensive study of the etiologic importance of infection. The streptococcus has been implicated most often, largely on the basis of epidemiologic studies suggesting that a common etiologic agent is involved in allergic purpura and in acute post-streptococcal glomerulonephritis.<sup>24</sup> However, antistreptolysin O (ASO) titers and attempts to isolate beta-hemolytic streptococci have failed to provide evidence as clear as there is in rheumatic fever and nephritis, that these organisms are causative factors.<sup>5,15,54,58</sup> The importance of hypersensitivity to bacterial products was suggested in one study, in which delayed skin hypersensitivity to vari-

**Table 36-2. The Appearance and Associated Clinical Features of Various Forms of Purpura**

<i>Disorder</i>	<i>Appearance*</i>	<i>Distribution</i>	<i>Associated Features</i>
Allergic purpura	Highly variable: small ecchymotic lesions on erythematous maculopapular base; urticarial lesions; bullae, ulcers in some cases	Symmetric, proximal: extremities, legs and buttocks	Lesions pruritic; ancillary joint and abdominal symptoms; generalized bleeding absent
Purpura fulminans	Large symmetrical spreading ecchymoses, circumscribed skin infarcts; petechiae uncommon	Often symmetric: distal extremities, genitalia	Symmetric gangrene of digits and distal extremities; fever, severe prostration; generalized bleeding and coagulation abnormalities common
Scurvy	Petechiae: often around hair follicles; ecchymoses: large subcutaneous hematomas	Often symmetric: "saddle" area of thighs and buttocks	Lassitude, pain in limbs; evidence of periosteal hemorrhage in children; generalized bleeding; other avitaminoses and positive reaction to tourniquet test common
Autoerythrocyta sensitization	Solitary: often large spreading purplish to reddish ecchymoses on an erythematous edematous base	Proximal extremities: antero-lateral thighs and legs; abdomen: rare on back	Prodromata: lesions often painful and tender; nausea, vomiting and other generalized symptoms; hysterical and neurotic symptoms; menorrhagia, hematuria, and epistaxis common; positive reaction to skin test
Thrombocytopenic purpura	Purple to black petechiae; superficial ecchymoses of varying size and shape	Anywhere: most common in dependent areas, sites of venous constriction and "pressure" points	Generalized bleeding from mucosal surfaces common

\*Purpuric lesions appear and regress in crops; are not elevated, do not blanch on pressure

ous bacterial vaccines, including those prepared from streptococci, was demonstrated in patients with allergic purpura but not in controls.<sup>40</sup> It also has been suggested that allergic purpura is a form of "immune complex" disease involving IgA antibody and an unidentified antigen,<sup>55</sup> but the evidence for this hypothesis is not altogether convincing.

The presence of fibrin within the glomerular deposits led to the suggestion that diffuse intravascular coagulation was involved in the pathogenesis of allergic purpura,<sup>56</sup> a hypothesis which is inconsistent with other data demonstrating normal fibrinogen turnover

rates and the absence of fibrinogen degradation products.<sup>55</sup>

### Incidence

The syndrome is seen most often in children, less commonly in adolescents and young adults, and rarely in older persons. The average age of onset in two series was 5.6 years<sup>37</sup> and 5.2 years,<sup>47</sup> respectively. While the condition is uncommon in children less than two years of age, in a series of 139 patients the age range was from 10 months to 12½ years.<sup>37</sup> Males predominate in a ratio

of 3:2.<sup>18,54</sup> In Great Britain, spring and autumn peaks of incidence have been observed.<sup>15,37</sup>

### Clinical Picture

The onset, signs, symptoms, and course of allergic purpura are quite variable. Headache, anorexia, fever, or abdominal pain may usher in an attack, or pain in and around the joints may be the first complaint. Purpura may be a relatively minor component of the clinical picture, and in some attacks may even be absent. Intermittent fever of moderate degree is common.

**SKIN LESIONS.** Purpura usually is associated with one or more of the common cutaneous manifestations of allergy, eg, urticaria, erythema (Table 36-2 and Fig. 36-1), and the resulting skin lesions may "run the gamut of the skin atlas."<sup>43</sup> The lesions usually are located on the proximal portions of the extremities, particularly the legs and on the buttocks, often are symmetric in distribution, and may appear and regress in crops. In contrast to most other purpuric lesions, they may be accompanied by itching or paresthesias.

Osler,<sup>43</sup> who described the lesions in great detail, pointed out that there may be four major types of lesions: (1) purpura which may be simple but more often is accompanied by swelling; blebs may be found which have the appearance of herpes on a purpuric or hyperemic base or there may be bullae or even pemphigoid lesions (Fig. 36-2); (2) urticarial wheals or angioneurotic edema; (3) diffuse erythema, with or without swelling; (4) necrotic areas which may be followed by the formation of ulcers.<sup>31</sup>

Gairdner<sup>24</sup> described the evolution of skin lesions which he regarded as very characteristic. Small, discrete urticae first appear upon the extensor surfaces of the upper and lower limbs. Within a few hours these begin to change to pink maculopapules, becoming less raised and darker in color. Dusky red macules which do not fade on pressure are found the next day and these may coalesce

Fig. 36-1 Hemorrhagic and erythematous lesions in a patient with Henoch-Schönlein purpura

to form larger patches (Fig. 36-3). As regression takes place, the red color takes on a purple hue before fading to brown. Frankly hemorrhagic lesions are uncommon.

**GASTROINTESTINAL TRACT.** Serohemorrhagic effusions into the bowel wall may lead to abdominal colic, nausea, and vomiting in approximately 50% of cases. When such abdominal symptoms predominate, the disorder is often referred to as Henoch's purpura.<sup>30</sup> As stated earlier, these symptoms may develop before the purpuric eruption appears; needless operations have been performed as a result.<sup>1,7</sup> Colic is the most common symptom. The pain may radiate to all parts of the abdomen, but usually is midabdominal in location. In Osler's experience<sup>43</sup> the right lower quadrant was spared, and colic occurred most often at night. Tenderness is often present, but muscular rigidity is absent. Diarrhea is uncommon, but mucoid or bloody stools may be passed. Gross melena,

Fig 36-2 Bullous lesions in a patient with allergic purpura (Courtesy of Dr Peyton Weary)

hematochezia, and intestinal perforation<sup>44</sup> are rare complications.<sup>27</sup> Tenesmus may be noted and constipation may be so stubborn as to suggest obstruction. Intussusception has been observed<sup>93</sup> and is more common in children than in older subjects. Protein-losing enteropathy was reported in five cases.<sup>32</sup> Small isolated red spots may be seen in the buccal mucosa. Gastrointestinal roentgenograms reveal various nonspecific abnormalities.<sup>29,43,49</sup>

**MUSCULOSKELETAL SYSTEM.** The term Schönlein's purpura refers to allergic purpura in which joint pain and tenderness are prominent.<sup>51</sup> The knees, ankles, and wrists are most commonly involved.<sup>49</sup> These symptoms may precede the onset of abdominal pain or purpura.<sup>51</sup> The pain is rarely as intense as in acute rheumatic fever, and is not strikingly influenced by salicylates. Periarthicular swelling is common, but hemarthrosis does not occur. Edema may be present, particularly of the dorsum of the hands and feet.

**GENITOURINARY TRACT.** Renal involvement can be demonstrated at some time during the course of the disease in 22 to 60% of the patients.<sup>25,47,54-58</sup> In the majority, this is asymptomatic and completely reversible, but in 5 to 10% the picture of chronic or subacute glomerulonephritis develops.

In an occasional patient<sup>43</sup> the picture of fulminating acute glomerulonephritis with hypertension, uremia, and early death is seen.<sup>25</sup> Such a fatal course is more common in adults than in children.<sup>8</sup> Rarely, the nephrotic syndrome develops.<sup>25</sup> Whether or not these cases represent a fundamentally different disorder remains uncertain.<sup>16</sup>

**MISCELLANEOUS.** Wheezing and dyspnea have been described<sup>43</sup> but are unusual. Acute respiratory obstruction due to edema of the glottis is a serious complication but fortunately is rare. Myocardial necrosis,<sup>36</sup> hepatomegaly,<sup>3</sup> and hemorrhage into the testis<sup>3</sup> have been reported. Involvement of the nervous system<sup>33</sup> and special sense organs may

Fig 36-3. Erythematous macular lesions in a patient with allergic purpura (Courtesy of Dr Peyton Weary)

lead to such diverse symptoms as transient attacks of paresis; epileptiform convulsions; facial nerve palsy<sup>34</sup>; hemorrhages into the eyelids, conjunctiva, or retina; optic atrophy; iritis; and ophthalmitis.<sup>9,28</sup>

### Laboratory Findings

Examination of the blood may reveal modest neutrophilia or eosinophilia. Hemorrhage is rarely sufficiently marked to produce anemia. The reaction to the tourniquet test may be positive,<sup>45</sup> but the results of other tests of hemostasis and blood coagulation, including the platelet count and the bleeding time usually are normal.

Gross hematuria is uncommon. Microscopic hematuria, red cell casts, proteinuria, and mild azotemia are common but often

transient findings. Examination of the stools may reveal blood. The ASO titer usually is normal.<sup>55,142</sup> Elevated levels of IgA globulins have been demonstrated in approximately 50% of the patients.<sup>53</sup>

### Differential Diagnosis

The skin lesions of allergic purpura often are characteristic. This disorder should be suspected whenever erythematous or urticarial lesions are associated with purpura. A history of previous attacks of joint symptoms when the main complaint is referred to the abdomen, and vice versa, also is suggestive. Serious diagnostic difficulties usually arise when purpura is not obvious or is absent altogether. In such cases, the symptoms may suggest a variety of conditions. For example, bouts of abdominal pain accompanied by fever, leukocytosis, or melena cannot be readily distinguished from symptoms due to acute abdominal conditions which call for surgical intervention. When renal involvement is prominent, allergic purpura is readily mistaken for acute post-streptococcal glomerulonephritis. The serum complement or  $\beta_2$  globulin levels usually are low in glomerulonephritis,<sup>5,56</sup> but are normal in allergic purpura.<sup>55,112</sup> When joint symptoms predominate, a normal ASO titer is helpful in excluding the possibility of acute rheumatic fever.<sup>4,7</sup>

Skin and renal biopsies may be helpful in an occasional case, but the essentially non-specific findings discussed below cannot be regarded as diagnostic.<sup>142</sup> It is as yet uncertain whether various subtle ultrastructural features of the renal lesion as revealed by electron microscopy are more specific.<sup>1,12</sup>

### Course; Prognosis

Allergic purpura usually is a self-limited disorder and individual attacks last from one to six weeks, during which the symptoms may wax and wane in intensity. Recurrences, after an interval usually of days but sometimes of weeks or months, are very common, and in one case were observed over a period

of 17 years.<sup>18</sup> The recurrent clinical manifestations do not necessarily resemble those of the initial episode.

The immediate prognosis usually is favorable unless such complications as intussusception, hemorrhage into the nervous system, or edema of the epiglottis occur. In 50% of 49 patients having initial renal involvement, the urine was found to be normal three months later. However, in a significant number of patients, renal involvement may become chronic. Recovery was not observed in any patient in whom abnormal urinary findings were present over a period of two years or more.<sup>34</sup> It has been suggested that renal sequelae of allergic purpura are one of the causes of "chronic renal disease of unknown etiology" in adults.<sup>35</sup>

### Treatment

Because of the tendency of allergic purpura to remit and recur spontaneously, the efficacy of various therapeutic measures is difficult to evaluate. In the majority of cases, only symptomatic therapy is required. If it can be discovered, the inciting agent should be removed or avoided. Elimination diets may be tried. Results of treatment with antihistamines and adrenocorticosteroids, with few exceptions,<sup>11</sup> have usually been equivocal or disappointing. Corticosteroids, eg, prednisone, 2 mg/kg/day up to a maximum of 50 mg daily,<sup>36</sup> may provide symptomatic relief of joint and abdominal pain in some patients.<sup>11</sup> Immunosuppressive drugs have produced encouraging results in a few patients.<sup>27-30</sup> In the hope of reducing the incidence of chronic nephritis, bed rest has been recommended.<sup>1</sup>

### Pathology<sup>10,142</sup>

The skin reveals perivascular infiltration of the dermis and swelling and degeneration of endothelial cells. Numerous leukocyte platelet thrombi are present in small dermal vessels. In severe cases a necrotizing arteriolitis has been observed.<sup>21,24</sup> Kidney biopsies<sup>28a</sup>

obtained during the acute phase of the disease reveal focal fibrinoid deposits and endothelial proliferation within scattered glomeruli. Specimens taken during recovery show focal glomerular scars.<sup>38</sup> This contrasts with the diffuse and uniform changes observed in acute and subacute glomerulonephritis. More diffuse glomerular lesions have been found in some patients with chronic disease.<sup>30</sup> The lesion most commonly seen in the gastrointestinal tract at operation is extravasation of blood or serosanguineous fluid into the wall of the small intestine<sup>4</sup>; edematous, scarlet-colored segmental lesions also have been described.<sup>7</sup>

### Drug-Induced Vascular Purpura

A multiplicity of drugs and chemicals (Table 36-1) may produce striking generalized purpuric eruptions. Although often quite alarming to the patient, such drug-induced vascular purpura usually subsides promptly when use of the drug is discontinued. The purpura is not associated with other bleeding manifestations, and is thus of little clinical consequence.<sup>1</sup> Owing to the benign nature of the disorder, it is probable that unreported cases of vascular purpura have developed following the use of many drugs in addition to those listed in Table 36-1.

The pathophysiology of these lesions is poorly understood. Purpura develops in only an occasional patient who has taken these drugs and apparently is the result of individual idiosyncrasy. An autoimmune basis has been suggested, but direct evidence to support this hypothesis is lacking. Serologic studies have failed to demonstrate humoral antibodies.

The hemorrhagic skin infarcts which may develop following the administration of coumarin anticoagulants (page 1245) appear to represent an unusual form of drug-induced vascular purpura.

### Purpura Fulminans

The term "purpura fulminans" was applied by Henoch to a unique disorder characterized

by sudden onset, fever, prostration, symmetric circumscribed ecchymoses and infarcts of the skin, and frequently by gangrene of the extremities (Table 36-2). The major initiating factor in this disorder appears to be diffuse vascular injury, but in many well-studied cases there is clear evidence for diffuse intravascular coagulation. This disorder is discussed further on page 1219.

The term "purpura fulminans" also has been used in a less restricted sense to apply to any severe purpura of rapid onset, eg,

meningococcemia, particularly when associated with the Waterhouse-Friderichsen syndrome.

### Purpura Associated with Infections

A wide variety of infections may produce purpura by means of vascular damage (Table 36-1 and Fig. 36-4). This may result from direct endothelial injury by the infectious agent, eg, rickettsia, some viruses, meningo-

Fig 36-4. Purpuric lesions in a patient with scarlet fever. There was no thrombocytopenia (From Fox and Enzer,<sup>23</sup> courtesy of the authors and the American Journal of Medical Science)

cocci; in other cases, autoimmune processes, bacterial products, or toxins may be responsible.<sup>125</sup> In bacterial endocarditis, the purpura is due to embolic occlusion of the microvasculature, and white-centered hemorrhagic lesions may be seen. Purpura associated with meningococemia also may be due, in part, to emboli. In many cases, thrombocytopenia (page 1101) and diffuse intravascular coagulation (Chapter 38) contribute to the purpura associated with infectious diseases.

## Structural Malformations of Vessels and Perivascular Tissues

### Hereditary Hemorrhagic Telangiectasia

In hereditary hemorrhagic telangiectasia, a vascular malformation involves vessels throughout the body which are dilated, tortuous, and disorganized. Widespread telangiectatic lesions of the skin and mucous membranes are the principal manifestation of the disorder. The walls of affected vessels are markedly thinned, vascular support is poor and vascular contractility is diminished. As a result, bleeding may follow trivial trauma or arise spontaneously. Hereditary telangiectasia was first described by Sutton<sup>65</sup> in 1864 and received the attention of Rendu<sup>66</sup> in 1896, Osler<sup>67</sup> in 1901, and Weber<sup>68</sup> in 1907, by whose names the condition is sometimes known.

### Etiology, Genetics

The vascular abnormality is inherited as an autosomal dominant trait of high penetrance.<sup>67</sup> Some individuals rarely or never suffer from hemorrhage and this may explain the apparent skipping of the members of a whole generation. Painsstaking examination usually reveals signs of the disease in one of the parents. Rarely, a new mutation occurs or the lesions are all internal. The manifestations in the offspring of two affected parents were severe and extensive from birth, and death occurred at 11 weeks of age.<sup>64</sup>

The condition probably is not as rare as was once thought. In Utah, the polygamy of the pioneers led to the wide transmission of the trait, as the family tree shown in Figure 36-5 testifies. Affected kindreds have been chiefly of Anglo-German, Latin, Scandinavian, or Jewish stock. There are three reports of the disorder in the Negro.<sup>69</sup>

### Clinical Picture

The lesions range in size from pinpoint to about 3 mm in diameter. They are bright red or purple, and are most commonly found on the face, lips (Fig. 36-6), tongue, ears, conjunctivae, and the palmar and plantar surfaces<sup>66</sup> (Fig. 36-7). They usually are flat. Characteristically, they blanch on pressure (Table 36-3). To observe this, pressure may be applied by means of a glass slide through which the color of the lesion may be observed. Purpura and ecchymoses are not seen, and, unlike purpuric lesions, telangiectases are permanent. The telangiectases may form nodular vascular tumors the size of a split pea (Fig. 36-8), and sometimes they are spider-like, particularly in elderly patients. The last-named lesions, however, are not characteristic of the disorder.

The most common symptoms are those of hemorrhage and anemia. In general, telangiectases of the skin are less likely to bleed than are those of the mucous membranes. Epistaxis is especially common, but bleeding may come from telangiectases in any location such as the tongue or mucous membranes of the mouth, or the gastrointestinal,<sup>102</sup> respiratory, or genitourinary tracts.<sup>76</sup> Hemorrhage even into the brain and retina<sup>71</sup> has been attributed to the presence of telangiectases, but telangiectatic lesions have not been demonstrated in all instances. Bleeding from wounds or following surgical procedures is uncommon. Pallor may or may not be present. Splenomegaly and hepatomegaly have been found in a few cases, and are most common in older patients.<sup>75,91</sup>

The telangiectases may be found in childhood but they increase in number with advancing age. Bleeding may not commence

Fig 36-5. Family tree showing six generations of a family of 'bleeders' whose progenitor had four wives<sup>72</sup> Those persons who were examined were found to have hereditary hemorrhagic telangiectasia (Courtesy of Dr F E Stephens)

Fig 36-6 Typical telangiectases on the lips of a patient with hereditary hemorrhagic telangiectasia

Fig. 36.8 Photograph and drawing of the head of the patient whose hands and feet are shown in Figure 36.7. Four types of vascular lesions were present. Inset B is the typical telangiectasis. C is a spider angioma.

reactions to the tourniquet test<sup>101</sup> and prolongation of the bleeding time have been recorded. In an occasional patient, diminished *in vivo* platelet adhesiveness<sup>81</sup> and other findings suggestive of von Willebrand's disease<sup>86</sup> (page 1179) have been encountered. These findings have led to speculation regarding a nosologic relationship between the two disorders.<sup>86</sup>

### Differential Diagnosis

Diagnosis of hereditary hemorrhagic telangiectasia is seldom difficult because the triad of habitual hemorrhage, multiple telangiectases, and familial occurrence is so characteristic. The telangiectases must be differentiated from purpuric lesions, spider telangiectases of liver disease, cherry angiomas, and the various venous abnormalities which are frequently seen in elderly persons, eg, venous lakes, venous stars, caviar lesions on the under surface of the tongue, and senile telangiectases of the scrotum (angiokeratoma of Fordyce) (Table 36-3). When externally visible lesions are lacking or are overlooked, perplexing diagnostic problems may result. In such cases, erroneous diagnoses such as pernicious or other forms of anemia, peptic ulcer, or Banti's syndrome have been made. This disorder should always be considered in the differential diagnosis of recurrent or intractable gastrointestinal bleeding of obscure etiology.<sup>102</sup> In such cases, visceral angiography may be of great help in establishing the diagnosis.<sup>79</sup>

Pulmonary arteriovenous fistulas are best demonstrated by fluoroscopy or angiocardiology. Ordinary roentgenograms may not always reveal the lesions.<sup>70</sup>

The telangiectatic skin lesions of scleroderma, and those of a related syndrome characterized by Raynaud's phenomenon, sclerodactyly, and subcutaneous calcinosis, are virtually identical in appearance, but are most common on the hands, seldom bleed, and are rarely found in the gut.<sup>65,99,103</sup> The skin lesions of the rare angiokeratoma corporis diffusum universale (CDU) (Fabry)<sup>119</sup> may be confused with those of hereditary telangi-

Fig. 36-9. Lesions resembling purpura in a patient with *angiokeratoma corporis diffusum universale*

ectasia as well as with petechiae (Table 36-3 and Fig. 36-9). This disorder (page 1340) is an inherited abnormality of glycolipid metabolism resulting from deficiency of a ceramide-trihexoside-cleaving enzyme. It is characterized by widespread involvement of the media of blood vessels including the renal and pulmonary vasculature.<sup>134</sup>

### Treatment

Only symptomatic and supportive therapeutic measures are available. Oxycel, Gel-foam, or similar topical hemostatic agents usually are effective in controlling hemorrhage from accessible sites, and they have the added advantage that they do not need to be removed after the bleeding has stopped. Nasal tamponade may be necessary in the treatment of epistaxis. A useful device consists of a finger cot placed over the end of a small catheter and tied snugly with fine thread. This is lubricated, inserted well back in the nostril, and inflated. Firm uniform

pressure is thus applied to the entire interior of the nasal fossa. After the bleeding has stopped, the cot is slowly deflated and withdrawn or allowed to drop out of the nostril.<sup>74</sup>

Although it is possible to destroy the primary lesions by *cautery* with escharotics such as silver nitrate or by means of electrocoagulation,<sup>74</sup> such therapy is usually futile since satellite lesions soon form nearby. Electrocoagulation has proved more effective in destroying lesions about the lips, the oral cavity, and on the cutaneous surface of the body than in the nasal fossae. Septal dermoplasty was reported as being effective in permanently controlling epistaxis.<sup>59</sup> Radium, although successful immediately, eventually produces atrophy and dryness of the nasal mucosa and may be followed by perforation of the septum.

The systemic administration of estrogen alone<sup>81,83</sup> (0.25 to 1.0 mg ethinyl estradiol per day) or in combination with a progestational steroid<sup>73</sup> is claimed to be effective in reducing the frequency and severity of epistaxis. These hormones induce squamous metaplasia of the nasal mucosa, which presumably protects the vascular lesions from trauma.<sup>128</sup> In males, feminizing side effects may be minimized by the concomitant administration of methyl testosterone (2.5 to 5.0 mg daily).

*Arteriovenous fistulas*, if symptomatic, should be treated surgically. Unfortunately, the lesions often are more diffuse than suspected preoperatively and recurrences are common.

Iron deficiency anemia should be treated with sufficient iron to replenish tissue stores (Chapter 17). The intravenous administration of massive amounts of iron dextran compounds may be necessary in the face of continued blood loss.<sup>69</sup>

### Pathology

The walls of the affected vessels are extremely thin, consisting merely of a layer of endothelium.<sup>80</sup> The veins are involved primarily and arterial involvement is inconspicuous. The telangiectases have been found at

autopsy<sup>85,91</sup> in all major organ systems and in each the venous defect was diffusely distributed.<sup>64</sup> The large arteriovenous aneurysms found clinically in some patients may be only the larger counterparts of widespread telangiectases in the pulmonary tissue.<sup>100</sup>

### Hereditary Disorders of Connective Tissue

Abnormal bleeding is a common and clinically significant complication of the various hereditary disorders of connective tissue. In the Ehlers-Danlos syndrome and in osteogenesis imperfecta, qualitative and quantitative abnormalities of collagen, and possibly of elastin as well, presumably underlie the vascular abnormality. These result in vascular fragility and bleeding because of deficient extravascular and perivascular tissue support. Large ecchymoses and hematomas are common, but virtually all bleeding manifestations have been described.<sup>148</sup> Various abnormalities of platelet function, and rarely of blood coagulation, may contribute to the bleeding in an occasional patient. In a related disorder (hydroxylysine deficient collagen disease), easy bruising was the only hemorrhagic manifestation.<sup>116a</sup> In pseudoxanthoma elasticum, a wide variety of hemorrhagic manifestations is common, and subarachnoid and gastrointestinal bleeding are the most common causes of death.<sup>36</sup> There is some evidence that the fundamental vascular defect in this disorder is a structural abnormality of elastic fibers in small arteries.

Diagnosis is made on the basis of the associated clinical findings, which usually are characteristic. There is no known therapy.

### Acquired Disorders of Connective Tissue

#### Scurvy

Scurvy may be associated with serious bleeding manifestations, including persistent gingival bleeding and hemorrhage into the subcutaneous tissues and muscles.<sup>113</sup> Petechiae often develop in a characteristic "sad-

Fig. 36-10 Perifollicular petechiae in scurvy (From Weary,<sup>141</sup> courtesy of the author and Archives of Dermatology.)

dle" distribution (medial surface of the thighs, buttocks) and are most conspicuous around the hair follicles<sup>36,145</sup> (Table 36-2 and Fig. 36-10). Subperiosteal hemorrhages are characteristic of infantile scurvy but are very rare in adults. Bleeding is attributed to a defect in the endothelial lining and perivascular supporting tissues of small vessels. This is due to deficient synthesis of collagen and intercellular cement substance, but the biochemical basis for this defect remains obscure despite intensive study. The vascular abnormality may be complicated by disordered platelet function in some cases (page 1132). An abnormality in the contact phase of blood coagulation has been described in scorbutic guinea pigs.<sup>121</sup> Evidence that bleeding in scurvy is due to deficiency of a poorly characterized flavone ("vitamin P") is unconvincing.<sup>139</sup>

Fig 36-11 Senile purpura

A positive reaction to the tourniquet test is commonly seen and the bleeding time is occasionally prolonged. With these exceptions, the results of laboratory studies of hemostasis and blood coagulation are normal. Mild thrombocytopenia and other evidence of associated folic acid deficiency (Chapter 14) are not uncommon.

The oral administration of ascorbic acid (in adults, 1 g per day in divided doses; in infants, 50 mg) rapidly abolishes all hemorrhagic manifestations. Intravenous therapy offers no advantages, since the major proportion of the vitamin administered by this route is lost in the urine.

### Senile Purpura

Senile purpura is a chronic disorder of the elderly characterized by relatively distinctive red to purple ecchymotic spots on the ex-

tensor surfaces and radial borders of the forearm (Fig. 36-11), and the backs of the hands and neck.<sup>160</sup> The lesions range up to 4 cm in diameter. They usually arise spontaneously, but may result from very trivial pressure, eg, eyeglasses on the bridge of the nose (Table 36-2). The basic defect is one of degeneration and loss of dermal collagen, elastin, and subcutaneous fat. The distribution of the lesions of senile purpura corresponds in general to areas subjected to life-long exposure to actinic irradiation.<sup>142</sup> There is good evidence that the purpura is the result mainly of shearing injury of small dermal vessels which results from the hypermobility of the skin over underlying tissues.<sup>154</sup> Senile purpura may persist for weeks, seldom reveals the sequential pigmentary changes normally seen with other ecchymoses, and often leaves a residual brownish pigmentation. The indolent nature of the lesions has been attributed to inadequate mobilization of extravasated hemoglobin due to deficient macrophage function.<sup>154</sup> Liver disease was commonly associated in one series.<sup>118</sup> There is no therapy of proven value, and reports of the efficacy of ascorbic acid have not been confirmed.<sup>108</sup> Similar skin lesions are seen in a variety of debilitating disorders (*purpura "cachectica"*).

Vascular fragility manifested by "easy bruising" from trivial trauma is a predictable pharmacologic effect of the prolonged administration of moderate to large doses of corticosteroids. In terms of appearance, histopathology, and indolent course, the lesions resemble those of senile purpura. Similar abnormalities presumably are responsible for the purpura which may be seen in Cushing's disease.

## Miscellaneous Vascular Purpuras

### Autoerythrocyte Sensitization and Related Disorders

Autoerythrocyte sensitization is an uncommon disorder characterized by spontaneous

painful ecchymoses. Often heralded by prodromal stinging or burning, the lesions usually are surrounded by erythema and edema and may enlarge progressively (Table 36-2). They are commonly associated with headache, nausea, and vomiting, and occasionally with intracranial, genitourinary, and gastrointestinal bleeding as well.<sup>150</sup> In the majority of patients, similar ecchymotic lesions can be reproduced by the intradermal injection of autologous whole blood,<sup>123</sup> washed red cells, red cell stroma,<sup>4</sup> or even phosphatidylserine derived from the red cell membrane.<sup>126</sup> This relatively specific laboratory finding has led to the hypothesis that the purpura is the result of autosensitization to some component of the red cell membrane. In most of these patients, the "sensitizing incident" was unclear,<sup>150</sup> but in many there was a past history of severe trauma with bruising.

The disorder has occurred almost exclusively in women of middle age, and several observers have suspected that emotional factors may play an important pathogenetic role.<sup>106, 149, 150</sup> Psychiatric study revealed the propensity of such patients to express emotional problems in a physical form through both hysterical mechanisms and psychophysiologic reaction. Others manifested a prominent element of masochism in their character. Purpuric bouts were found to occur at times of emotional stress. Psychologic testing has revealed a remarkably uniform personality pattern characterized by difficulty in handling aggressive feelings and by other features which favor the view that this condition may be psychosomatic in nature.<sup>111</sup> In four patients,<sup>106</sup> purpura apparently was induced by hypnotic suggestion. This remarkable and important observation should be confirmed.

Autoerythrocyte sensitization may, thus, be a psychopathologic entity and certainly deserves further study from this point of view. The relation of this form of purpura to the hemorrhagic stigmata of religious connotation, which from time to time have received wide attention, has been considered.<sup>151</sup> Like the latter, in some instances of autoerythro-

cyte sensitization the purpura was shown to be factitious.<sup>114, 137</sup>

The clinical features of DNA auto-sensitivity<sup>112, 140, 152</sup> resemble those of autoerythrocyte sensitization. The acute and painful ecchymoses are confined to the extremities and can be produced by the intradermal injection of a solution of the patient's leukocytes or a solution of deoxyribonucleic acid (DNA) into the skin of the extremities. *In vitro* incubation of these substances with deoxyribonuclease, chloroquine, or primaquine abolishes this effect. Similar injections of ribonucleic acid fail to produce hemorrhages. Skin from an extremity which has been grafted to the trunk fails to react, but skin from the trunk will react if grafted to an extremity. The condition appears to represent localized hypersensitivity to DNA. In yet another similar disorder,<sup>133</sup> purpura could be reproduced by the intradermal injection of autologous hemoglobin.

These disorders may persist for years, often with remissions and exacerbations, and, in contrast to most other forms of vascular purpura, they may be severely debilitating. There is no treatment of proven value. Corticosteroids and antihistamines have usually been ineffective, and psychotherapy is seldom of permanent benefit. In DNA auto-sensitivity, treatment with chloroquine, primaquine, or hydroxychloroquine produces a dramatic clinical response, but relapse follows cessation of drug therapy.

#### Purpura in Association with the Paraproteinemias

In purpura associated with the paraproteinemias (Chapter 53), bleeding is an important clinical problem, but the hemostatic defect is complex, and the contributory roles of platelet dysfunction (page 1130), coagulation abnormalities (page 1211), and thrombocytopenia are difficult to assess in the individual case. In many patients, vascular abnormalities appear to predominate, and have been attributed to a direct or indirect

effect of the abnormal protein, eg, hyperviscosity and red cell "sludging" with thrombosis, a direct toxic effect of paraproteins, and even an autoimmune process.<sup>112</sup> There is no convincing evidence for any of these hypotheses.

Primary hyperglobulinemic purpura<sup>125, 159, 161, 163</sup> is a disorder most commonly seen in women which is characterized by hyperglobulinemia of the polyclonal type, and recurrent acute episodes of purpura, especially after unusual exertion, prolonged standing or excessive pressure from garments.<sup>108a</sup> Lesions are most common on the lower extremities, frequently are associated with premonitory itching, stinging, and erythema, and commonly result in progressive deposition of pigment.<sup>124</sup> The disorder thus resembles Schamberg's progressive pigmentary purpura.<sup>112</sup> Immunoelectrophoretic studies have demonstrated large amounts of anti-IgG globulins and antigen-antibody complexes formed therefrom.<sup>111</sup> Prolonged follow-up of patients with "benign" primary hyperglobulinemic purpura has revealed that the disorder frequently terminates in Sjogren's syndrome<sup>109, 124, 162</sup> and various other disorders.<sup>108a, 145</sup>

Secondary hyperglobulinemic purpura has been described in virtually every disorder characterized by hyperglobulinemia, but the specificity of such a diagnostic entity is questionable.<sup>159</sup>

Cryoglobulinemia of both the primary and secondary types (page 1640) gives rise to a relatively distinctive cold sensitivity syndrome, of which purpura is an important feature.<sup>127, 162</sup> Bleeding has been attributed to intravascular precipitation of cryoglobulins with resulting vascular damage,<sup>127</sup> and, in some cases, can be produced by placing an ice cube against the skin. Purpura is most common on the extremities, nose, ears, and face; bullae, chronic ulcerations, and cold urticaria are commonly associated. Cryofibrinogenemia produces a similar clinical picture,<sup>164</sup> presumably as the result of a related phenomenon, ie, the formation of cryoprecipitable complexes between fibrinogen,

plasma globulins, and various fibrinogen degradation products (page 438).

In Waldenström's macroglobulinemia, mucosal bleeding is more prominent than cutaneous hemorrhage, and epistaxis, gingival bleeding, and vaginal bleeding are common.<sup>143</sup> IgM globulins may also behave as cryoglobulins.

There are no specific measures for the treatment of bleeding in any of these conditions. Therapy of the underlying disorders is discussed in Chapters 52 and 53.

### Purpura Simplex and Related Disorders

The term "purpura simplex" usually refers to mild purpuric skin manifestations in otherwise healthy persons. The disorder appears to be particularly common in women ("devil's pinches") and often involves only isolated small ecchymoses on the legs. Exacerbations of such purpura during the menstrual period are not uncommon. In a hereditary form, spontaneous ecchymoses accompanied by positive reactions to the tourniquet test were observed in 88 members of 27 families.<sup>115</sup> All but four of those affected were females. Rheumatoid arthritis and rheumatic fever frequently were associated. Other cases have been reported<sup>120, 157</sup> which may or may not belong in this group. It is likely that, in some cases previously classified as "purpura simplex," bruising was the result of hereditary or drug-induced abnormalities of the platelet release reaction (Chapter 35). The disorder is usually of cosmetic significance only, and therapy is not required.

Violent muscular contractions, such as occur in whooping cough or convulsions, produce marked increases in intracapillary pressure which may cause vascular rupture and subcutaneous extravasations of blood. Such "mechanical purpura" usually involves the head, neck, and upper extremities. The term "orthostatic purpura" describes purpura which develops for the same reasons in the lower extremities in some persons on prolonged standing. Neither term is particularly useful, since it should be recognized that

purpura of any type tends to develop in areas of increased venous or capillary pressure. Although both "mechanical" and "orthostatic" purpuras may rarely be seen in normal persons, they are much more likely to be the result of a definable abnormality, e.g., thrombocytopenia.

Self-inflicted or factitious purpura is relatively common and on occasion may lead to serious diagnostic problems. Very bizarre purpuric lesions may result from self-flagellation with various objects, pinching, or sucking of the skin. The disorder is most common in women, and neurotic or psychotic symptoms usually are prominent. Factitious purpura must be distinguished from autoerythrocyte sensitization and the bleeding which results from self-administration of anticoagulant drugs (page 1245).

#### Purpura Associated with Skin Diseases and Other Conditions

In certain skin diseases<sup>142-144</sup> a purpuric eruption unaccompanied by thrombocytopenia may be encountered. These include annular telangiectatic purpura (Majocchi's disease), Schamberg's disease, pigmented purpuric lichenoid dermatitis, and angioroma serpiginosum. A number of chronic diseases may occasionally be associated with vascular purpura. The purpura described in some patients with acute glomerulonephritis and rheumatic fever<sup>131</sup> is similar to that seen in patients with allergic purpura. Purpura may result from diffuse vascular infiltration in generalized amyloidosis,<sup>105a,147,148</sup> polycythemia vera, myxedema, rheumatoid arthritis, and in as many as 15% of patients with hemochromatosis.<sup>158</sup> The multiple hemorrhagic lesions in the serous membranes, lungs, and other viscera following poisoning by viperidae and crotaline snake venoms are due in part to direct injury of the endothelial lining of capillaries and small veins.<sup>132</sup> Blood-borne tumor emboli are a rare cause of extensive purpura.<sup>156</sup> The purpuric manifestations of hepatic disease (page 1205) and azotemia (page 1129) are discussed in other sections.

#### **Special Aspects**

far greater scientific interest than their statistical frequency would suggest is evident from the number of books,<sup>37,40,41,163,213</sup> monographs,<sup>68,69,70,325</sup> and reviews<sup>39,304,324,326,375</sup> that deal with these experiments of nature.

The hereditary coagulation disorders produce quite similar signs and symptoms regardless of the particular factor that is lacking. Consequently, in the discussion to follow, only the clinical picture of hemophilia A, the most common variety, will be described in detail. Clinical features of the other forms that differ significantly from this prototype will be cited in the sections dealing with these very rare disorders.

The treatment of the hereditary coagulation disorders will be discussed in a single section (page 1183).

## **Nomenclature**

Many names have been proposed for the hereditary coagulation disorders, most of which incorporate the term "hemophilia," eg, pseudohemophilia, deuterohemophilia, parahemophilia, hemophiloid states A, B, C, and D.<sup>67</sup> Although the international Roman numeral designations (Table 10-I, page 410) represent a useful nomenclature for the coagulation factors, they do not provide descriptive names for conditions characterized by qualitative abnormalities of the various factors. The use of the term "hemophilia A" now appears to be preferable to factor VIII "deficiency," as will be evident from the dis-

**H**EREDITARY disorders of coagulation usually are the result of a deficiency or abnormality of a single plasma protein. As a consequence, they have provided a unique opportunity to study the phenomena of blood coagulation. The information that has resulted constitutes the cornerstone of our knowledge of this complicated and fascinating process. Hereditary coagulation abnormalities are the least common of the hemorrhagic disorders; the absolute incidence of the 30 or more disorders that comprise this group (Table 37-1) totals at most 1 in 10,000 to 15,000 persons<sup>190,217,369</sup> That they are of

cussion below, and the term "hemophilia B" is equally logical, since this disorder, also known as factor IX deficiency and Christmas disease, so closely resembles hemophilia A. The term "deficiency" will be retained with reference to the various other disorders, but it will be used in a functional sense, and should not be construed as having any pathophysiologic significance.

As with abnormal hemoglobins, qualitatively abnormal fibrinogens are now designated by the name of the city in which they were first discovered, eg, fibrinogen Paris.

Specific terms will also be used for variants of other disorders if such terms have become widely used, eg, factor X *Friuli*. Rapid changes can be expected in this field, and efforts directed toward standardizing this admittedly unsatisfactory nomenclature hopefully will be forthcoming.

## Principles of Pathophysiology

With the exception of fibrinogen and prothrombin, the coagulation factors are trace

proteins that have been difficult to study directly by chemical methods. Traditional laboratory measurements of their activity are "bioassays," which are inherently incapable of distinguishing between a *quantitative* abnormality, i.e., the absence of a requisite factor, and a *qualitative* abnormality, i.e., a non-functioning factor that is present in normal amounts. For many years it was generally assumed that the hereditary coagulation disorders were the result of a quantitative deficiency of trace plasma proteins. However, studies employing various immunologic techniques have now demonstrated that the absence of coagulant activity in the plasma of patients with these disorders may result from either deficient biosynthesis of a requisite protein, or defective biosynthesis, leading to the production of normal amounts of functionally inactive or functionally abnormal analogs<sup>326</sup> (Table 37-2).

The results of immunologic tests for the presence of coagulation factors usually are expressed as positive or negative for "cross-reacting material" (CRM). A positive test for CRM implies that a substance that is antigenically similar to the normal coagulation factor is present in the plasma. A coagulation disorder characterized by the presence of

such a substance often is termed a "CRM-positive" or "qualitative" disorder or variant; examples of such disorders are hemophilia A and factor XIII "deficiency." Some qualitatively abnormal coagulation factors produce abnormalities in coagulation that differ from those associated with a true quantitative deficiency of the factor. For want of a more specific term, such factors are termed *abnormal or aberrant factors*, in order to distinguish them from completely nonfunctional analogs. The most clearly defined disorders of this type are the dysfibrinogenemias, in which the abnormal fibrinogen is not totally nonfunctional, but may inhibit the function of normal fibrinogen. Other disorders characterized by "aberrant" coagulation factors include the Bm variant of hemophilia B, and some of the variants of factor X deficiency. Aberrant procoagulant proteins also may be synthesized in acquired "deficiencies" of the vitamin K-dependent factors (page 414).

A negative test for cross-reacting material indicates the absence of antigenically competent protein, and suggests that the disorder is due to deficient biosynthesis of the requisite factor. Such "quantitative" or "CRM-negative" disorders include afibrinogenemia and factor V deficiency. Presently available

techniques do not, however, exclude aberrations of sufficient magnitude to alter the antigenic determinants of the molecule, the presence of a precursor or subunit of the active coagulation factor, or the production of an analog that is catabolized at an abnormally rapid rate.<sup>326,328</sup>

## Hemophilia A

A severe and frequently fatal hemorrhagic diathesis that affected the male children of certain families was well recognized in antiquity. This is evident from the writings of Rabbi Simon ben Gamaliel (A.D. 2nd century) in the Talmud, and those of Maimonides, the Hebrew physician and philosopher, and Albucasis, the Arab (12th century).<sup>344</sup> The disease was clearly described by Otto<sup>217,296</sup> in 1803, and by Nasse who, in 1820, formulated the law of transmission of hemophilia.<sup>267</sup> The "bleeder's disease" was named hemophilia by Schönlein in 1839, and this term has since been used to refer to forms of the disorder that are inherited as X-linked recessive traits.<sup>77</sup> In 1893, Wright called attention to the prolonged coagulation time. Other early investigators in this field were Addis,<sup>5</sup> Sahli,<sup>346</sup> and Howell and Cekada.<sup>182</sup> Very complete monographs<sup>49,77</sup> cover the early literature.

### Pathophysiology

The hemostatic abnormality in hemophilia A (factor VIII deficiency, classical hemophilia) has at one time or another been attributed to a vascular defect, a platelet defect,<sup>126,259</sup> and abnormalities in the activity of tissue factor.<sup>235</sup> All of these hypotheses have been refuted. The apparent resistance of hemophilic platelets to aggregation and rupture<sup>182</sup> was found to be the result rather than the cause of the delayed coagulation.<sup>67,308,429</sup> The hypothesis that an excessive amount of a plasma inhibitor is responsible for the coagulation abnormalities in hemophilia was championed by Tocantins and his associates,<sup>394</sup> This hypothesis has gained few adherents,<sup>240,243</sup> and it is now generally ac-

cepted that the fundamental abnormality in hemophilia A is a deficiency or abnormality of a plasma protein.

Addis, in 1910,<sup>5</sup> demonstrated that a substance in normal plasma shortened the clotting time of hemophilic blood, thus suggesting that the disease is due to deficiency of a plasma protein. This substance (the anti-hemophilic factor, AHF, AHG, factor VIII) proved elusive and difficult to purify, and despite arduous efforts it is only within recent years that it has been studied in a semi-purified form (page 417). Such preparations of factor VIII are capable of correcting all coagulation abnormalities in the blood of hemophiliacs; they are equally effective *in vitro* and *in vivo*; their administration can prevent and arrest hemorrhage in patients with hemophilia A.

There is good evidence, however, that hemophilia A is not the result of deficiency of factor VIII; rather it is due to a *qualitative abnormality* of this protein. Thus, material which cross-reacts with antibodies to factor VIII was demonstrated in the plasma of each of 22 hemophilic patients from 21 different kindreds.<sup>432</sup> The amount of CRM, as quantified by immunoelectrophoresis, was the same in normal persons as in hemophiliacs. These results have been confirmed,<sup>31,383</sup> and normal or increased amounts of CRM have been demonstrated in the plasma of hemophiliacs by means of hemagglutination inhibition<sup>183,383</sup> and radioimmunoassay.<sup>184</sup> A quantitative variant of the disorder, in which CRM could not be demonstrated in the plasma, has been documented in approximately 5% of cases.<sup>31,84,384</sup> Available evidence thus suggests that a substance antigenically similar to factor VIII is present in normal amounts in the plasma of most patients with hemophilia A. This appears to be a nonfunctional form of factor VIII, which may be either a qualitatively defective form of this factor or a precursor (page 1180).<sup>326,328</sup>

### Genetics

Hemophilia A is the classic example of an X-linked recessive trait. The genetics of this

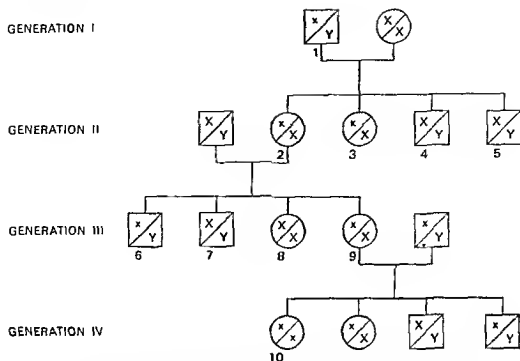

Fig 37-1 The inheritance of hemophilia A and hemophilia B. The pedigree is hypothetical. Key: normal X chromosome = X, abnormal X chromosome = x, male = square, female = circle, affected member = fully shaded square or circle, carrier = half shaded circle.

disorder have been intensively studied and frequently reviewed.<sup>49, 90, 150, 151, 194, 304</sup> In such a disorder, the defective gene is located in the X chromosome.<sup>52</sup> In males, who lack a normal allele, the defect is manifested by clinical hemophilia (Fig. 37-1, generation I, number 1). The affected male will not transmit the disorder to his sons (generation II, numbers 4 and 5) since his Y chromosome is normal. However, all of his daughters will be carriers of the trait since they inherit his X chromosome (generation II, numbers 2 and 3), but will be clinically unaffected due to the presence of a normal allele from the mother. The carrier female will transmit the disorder to one half of her sons (generation III, numbers 6 and 7) and the carrier state to one half of her daughters (generation III, numbers 8 and 9).

The severity of bleeding, ie, the *expressivity* of the genetic defect, varies from kindred to kindred in hemophilia A (Table 37-3). However, within a given kindred, the clinical

severity of the disorder is relatively constant, ie, relatives of severe hemophiliacs are likely to be severely affected.<sup>297</sup> These observations led to the suggestion that the degree of factor VIII deficiency depends on which of a series of abnormal alleles replaces the normal gene on the X chromosome.<sup>152, 310</sup> No conclusive evidence has yet been obtained that the factor VIII levels in normal subjects<sup>298, 305</sup> are genetically controlled.<sup>213</sup> Hemophilia A has been observed several times in *twins*.<sup>314</sup> Only in one somewhat equivocal instance has the disorder not appeared in both members of an identical pair.

It might be expected that, with random mating in a large population, a rare defect like hemophilia A would tend to die out after several generations, particularly since in the past the disorder was often fatal in childhood. That this has not occurred suggests that the mutation rate for the responsible gene may be unusually high.<sup>15, 100, 127, 309</sup> Consistent with this hypothesis is the fact that oo-ivi-

dence or history of abnormal bleeding is found in other members of the families of at least one third of all hemophiliacs.<sup>39</sup> The passage of the trait through a succession of carrier females or neonatal deaths may explain the negative family history in other instances. For practical purposes, therefore, a negative family history is of little value in excluding the possibility of hemophilia.

There is now good evidence that factor VIII production is regulated not only by the gene on the X chromosome, but also by one or more autosomal genes. This hypothesis has been established beyond doubt by the recognition of factor VIII deficiency in von Willebrand's disease, as discussed on page 1179. A report of hemophilia A with autosomal dominant transmission<sup>169</sup> appears to represent a variant of von Willebrand's disease.<sup>405b</sup> In another kindred, with otherwise typical X-linked recessive inheritance, unaffected males had low factor VIII levels, an observation suggesting that they were heterozygous for genes controlling factor VIII biosynthesis.<sup>389</sup> Still other genetic variants of hemophilia A have been reported.<sup>55</sup>

### Carrier Detection

The regularity with which the abnormal gene is suppressed by the normal allele in female carriers of hemophilia varies because of the *phenomenon of random X-chromosome inactivation* (the Lyon hypothesis). Thus, although the mean concentration of factor VIII in the plasma of heterozygous carrier females is approximately 50% of that present in normal women,<sup>32,108,261,297</sup> observed values scatter widely around this mean. Levels observed in carriers often overlap with those of the normal population,<sup>297</sup> but this is partly due to the large error of assay methods, and the wide range of factor VIII levels in normal persons.<sup>297</sup> One study suggested that assay of factor VIII will detect with reasonable accuracy about 75% of the true carriers in a potential carrier population.<sup>319</sup> Others have reported figures on the order of 35%, which

are more consistent with the experience of most investigators.<sup>406</sup>

Although the demonstration of subnormal levels of factor VIII by means of the usual assay methods strongly suggests the presence of the carrier state, the converse statement cannot be made with equal certainty, i.e., the presence of normal levels of factor VIII does not reliably exclude the carrier state.<sup>319</sup> Furthermore, pregnancy and anovulatory medications may increase the levels of factor VIII in carrier females<sup>27</sup> (page 421). Immunologic assays of factor VIII greatly improve the accuracy of carrier detection,<sup>27,102,326,432</sup> but are not as yet generally available.

### Hemophilia in the Female

Hemophilia has been well documented in human females.<sup>59,135,140,270,424</sup> The most common form is that seen in a minority of *heterozygous carriers*, discussed above, in whom X-chromosome inactivation occurs at an unusually early stage of embryogenesis and results in unusually low levels of factor VIII.<sup>32</sup>

A second cause of female hemophilia is a mating between an affected male and a carrier female (Fig. 37-1, generation IV, number 10).<sup>253,400</sup> One half of the female offspring of such a match would inherit two abnormal X chromosomes, one from the father and one from the mother. At one time it was suspected that such *homozygous female hemophilia* might be lethal and inhibit the development of the embryo. That this is not true was first suggested by the successful experimental production of hemophilia in a female dog.<sup>151</sup> Homozygous hemophilia has now been well authenticated in several women,<sup>253,400</sup> and resembles the disorder seen in affected males in all respects.

In several other instances of female hemophilia the disorder appeared to have developed *spontaneously*,<sup>10,237</sup> presumably as the result of a newly mutant gene. Rarely a *chromosomal abnormality* resulting in a hemizygous genotype in the female may be responsible, eg, 46 XX/45 X mosaicism,<sup>138</sup> 46 XY karyotype.<sup>273</sup>

## Incidence

Hemophilia A has been recognized in all areas of the world where adequate information is available.<sup>126</sup> The disorder seems to be rare among Chinese, and is uncommon in Negroes.<sup>65, 289</sup> Earlier data concerning the occurrence of hemophilia A certainly included persons with hemophilia B; many male patients afflicted with von Willebrand's disease and other persons with hereditary coagulation disorders probably were included as well. No doubt these data excluded many of the less severe cases.

Hemophilia A is the commonest of the hereditary coagulation disorders. The absolute incidence of the disorder has not been defined accurately, the best available estimates range from 1 in 20,000 to as high as 1 in 10,000 persons.<sup>190, 317, 369</sup>

The relative incidence of hemophilia A, as compared to the various other hereditary co-

agulation disorders, varies, depending on the particular population studied, but several major surveys, which reflect largely northern European and American populations, have revealed that an average of 80% of the cases of hereditary coagulation disorders were hemophilia A.<sup>274</sup>

## Clinical Manifestations

The most dramatic manifestation of hemophilia A is exsanguinating hemorrhage from a trivial traumatic injury. However, the most characteristic bleeding manifestations, such as hemarthrosis, often develop without significant trauma, and their frequency and severity generally are related to the blood level of factor VIII.<sup>39, 67</sup>

Three categories of severity may be arbitrarily distinguished (Table 37-3): (1) *Severe deficiency* (factor VIII level 0 to 2% of normal), which is clinically manifested by re-

**Table 37-3. Clinical and Laboratory Findings in Hemophilia A and Hemophilia B**

Severity	Factor VIII or IX Level (% of Normal)	Clinical Picture	Coagulation Tests		
			Coagulation Time	Prothrombin Consumption Test	Partial Thromboplastin Time
Severe	0-2	Hemarthrosis and spontaneous bleeding severe and frequent, crippling common	Prolonged	Abnormal	Prolonged
Moderate	2-5	Spontaneous bleeding and hemarthroses infrequent crippling uncommon serious bleeding from trivial injuries	Normal	Variable	Prolonged
Mild	5-25	Spontaneous bleeding and hemarthroses uncommon, unsuspected and serious bleeding from traumatic injuries and surgery, diagnosis may be missed	Normal	Normal	Variable
* Subhemophilia*	25-50	Moderate bleeding following major trauma or surgery, diagnosis often missed	Normal	Normal	Usually normal

peated and severe hemarthroses that almost invariably eventuate in crippling; such severe cases often are referred to as "classic" hemophilia. (2) *Moderate deficiency* (factor VIII level 2 to 5% of normal), which is associated with less frequent and less severe hemarthroses and seldom results in serious orthopedic disability. (3) *Mild deficiency*<sup>152</sup> (factor VIII level 5 to 25% of normal), in which hemarthroses and other spontaneous bleeding manifestations may be absent altogether, although serious bleeding may follow surgical procedures or traumatic injury.<sup>49</sup> Some authors include a fourth category termed "*subhemophilia*"<sup>67</sup> (factor VIII level 25 to 50% of normal), which results in no unusual bleeding except when the patient experiences serious trauma or a major surgical procedure.

### Hemarthrosis

Hemarthrosis is the most common, the most painful, and the most physically, economically, and psychologically debilitating manifestation of the hereditary coagulation disorders.<sup>50,91,200</sup>

**PATHOPHYSIOLOGY.** Bleeding presumably originates from the synovial vessels, and develops spontaneously or as the result of imperceptible or trivial trauma. Hemorrhage occurs into the joint cavity or into the diaphysis or epiphysis of the bone. In the *acute stage*, the synovial space is distended with blood. Muscular spasm further increases the intrasynovial pressure. Hemorrhage into the periarticular structures is a common complicating feature, and occurs most frequently around small joints.

The joint may regain normal function following the first episodes of hemarthrosis. More frequently, however, the absorption of intra-articular blood is incomplete, the retained blood produces chronic inflammation of the synovial membrane, and the joint remains swollen, tender, and painful for months or years. This has been referred to as the second stage of hemarthrosis, or the *stage of panarthrititis*.

Acute hemarthroses almost invariably

recur from time to time. With each recurrence, the synovium becomes progressively more thickened and vascular; folds and villi, which predispose to synovial injury during even minimal activity, may be formed. Together with the weakening of the periarticular supporting structures, this process predisposes the joint to recurrent episodes of bleeding. Repeated bouts of hemarthrosis, with the associated subchondral and synovial ischemia, result in progressive loss of hyaline cartilage, particularly at the margins of the joint. Large punched-out areas of destruction are sometimes produced by subchondral hemorrhages and, in the cancellous structure of the bone, cavitation may be caused by intraosseous hemorrhage. Through disuse, diffuse demineralization of the involved bones also may occur. Subperiosteal hemorrhages are not common.<sup>404</sup>

The *terminal stage* of hemarthrosis is not sharply differentiated from the panarthritic stage. In the larger joints, fibrous or bony ankylosis is common, but in the smaller articulations complete destruction may take place because of the weaker joint structure and the thinner cortices of the smaller bones.<sup>121</sup> Other permanent sequelae of hemarthrosis include atrophy and proliferation of bone, roughening of the articular surfaces with lipping and osteophyte formation, bone necrosis and cyst formation, stunted growth as the result of interference with the nutrition of the bone, and accelerated development and overgrowth of the epiphyses from excessive flow of blood to the growing epiphyses.<sup>50</sup>

**CLINICAL PICTURE.** The earliest symptom of hemarthrosis is pain, which in the acute form may be excruciating. Physical examination reveals muscle spasm and limitation of motion of the affected joint, which is usually held in a position of flexion. The joint may be warm and grossly distended and discolored, but external evidence of bleeding may be minimal or absent in chronically damaged large joints because of thickening of the articular capsule. Generally, only one joint is involved at a time, although bleeding

may develop simultaneously in two or more joints. The ankle frequently is the earliest joint involved, but the knee is the one most commonly affected and the one most often permanently crippled. Other joints that may be involved are the elbow, the hips,<sup>428</sup> wrists, shoulders, small joints of the hand and feet, the vertebral articulations,<sup>393</sup> and the temporo-mandibular joint.<sup>49</sup>

**RADIOLOGIC FINDINGS.** Radiologic changes range from a slight increase in the soft tissue shadows in the joint space, which results from distention or thickening of the synovium or joint capsule, to the aforementioned destructive changes that radiologically resemble advanced osteoarthritis<sup>330</sup> (Fig. 37-2).

#### *Subcutaneous and Intramuscular Hematomas*

Large ecchymoses and subcutaneous and intramuscular hematomas are common in hemophilia A, and characteristically spread within fascial spaces and dissect deeper structures. Subcutaneous bleeding may extend over as much as half the body and does so in a characteristic manner. At the site of origin the tissue is hard, indurated, raised, and purplish black. From this center, the hemorrhage extends in all directions "like ripples on a pond,"<sup>40</sup> with each successive concentric extension less deeply colored. The point of origin of the hemorrhage may be entirely absorbed, while the margin is still progressing. Intramuscular and subcutaneous hematomas may produce leukocytosis, fever, and severe pain, in the absence of significant discoloration of the overlying skin.

Hematomas may produce serious consequences from the *compression of vital structures*. Bleeding into the tongue, throat, or neck may develop spontaneously and is especially dangerous, since it may compromise the airway with surprising rapidity.<sup>227</sup> Gangrene may result from pressure on arteries,<sup>246</sup> and ischemic contractures are common sequelae of hemorrhage into the calves or forearms, eg, Volkmann's contracture. Peripheral nerve lesions of varying severity are common complications of hemorrhage into joints or

Fig 37-2 Roentgenogram of elbow and knee joints in a patient with hemophilia A. Thickening of synovium with deposition of calcium is shown in A and A', increased intercondylar notch in B, increased density decreased interarticular space in A, B, and C, and lipping along the borders of the joint surfaces in C.

muscles,<sup>365</sup> eg, femoral nerve compression due to hematomas of the iliacus.<sup>146</sup>

**PSOAS AND RETROPERITONEAL HEMATOMAS.** Spontaneous hemorrhage into internal fascial spaces and muscles of the abdomen is common in hemophilia A. Bleeding into or around the iliopsoas muscle produces pain of progressively increasing severity and tenderness, and, when on the right side, may closely simulate acute appendicitis. Partial or complete involvement of the femoral nerve may take place with the development of pain on the anterior surface of the thigh. The "psoas sign" is positive, and the hip is held in partial flexion. Paresthesias, partial or complete anesthesia, and ultimately weakness or paralysis of the thigh extensors with eventual muscular atrophy may ensue.

Retroperitoneal hemorrhage also is common, and may be mistaken for appendiceal abscess. Intraperitoneal hemorrhage and bleeding may occur elsewhere in the abdomen and may simulate virtually any acute intra-abdominal condition.

### *Gastrointestinal and Genitourinary Bleeding*

Hemorrhage from the mouth, gums, lips, and tongue is common and often serious. The eruption and shedding of deciduous teeth usually occurs without abnormal bleeding, but may be accompanied by hemorrhage that lasts for days or weeks. Epistaxis occurs in almost all patients, and may be of exsanguinating proportions.

Hematemesis, melena, or both are not uncommon. The source of the blood usually is in the upper gastrointestinal tract, and in the majority of patients in whom bleeding is persistent or recurrent it is found to originate from some organic lesion, most commonly a peptic ulcer or gastritis. Hemorrhage may be accompanied by abdominal pain, distention, increased peristalsis, fever, and leukocytosis. In one of our patients, gastrointestinal bleeding followed the ingestion of a peach stone. Intramural bleeding into the intestinal wall may result in intussusception or obstruction.

Hematuria, although much more common than gastrointestinal bleeding, is less often the result of a demonstrable pathologic condition in the genitourinary tract. The bleeding may arise in the bladder or in one or both kidneys, and may persist for days or weeks.<sup>304a</sup> When the hemorrhage begins to lessen and clots begin to form, ureteral colic may develop.

### *Traumatic Bleeding*

Patients with coagulation disorders seldom bleed abnormally from small cuts, such as razor nicks. Following larger injuries, however, hemorrhage out of all proportion to the extent of the injury is characteristic. This may persist as a slow, continuous oozing for days, weeks, or months, or may be massive and life-threatening.

*Delayed bleeding* is common. Thus, although hemostasis following an injury or a minor surgical procedure may appear to be entirely adequate, hemorrhage, often of sudden onset and serious proportions, may develop several hours or even days later. This phenomenon apparently is the result of the

fact that the processes of primary hemostasis are only temporarily effective. Delayed bleeding may occur in mild hemophilia, and is a significant hazard following minor surgical procedures, particularly those performed on an outpatient basis, eg, tooth extractions, tonsillectomy.

*Venipuncture*, if skillfully performed, is without danger to the hemophiliac because of the elasticity of the venous walls. If venipuncture is traumatic, a pressure dressing may prevent further complications. Subcutaneous, intracutaneous, and small intramuscular injections seldom produce hematomas if firm finger pressure is maintained for at least five minutes. *Lumbar puncture* can usually be carried out without serious risk if performed expertly but many prefer to administer factor VIII beforehand.

### *Miscellaneous Clinical Manifestations*

Infants are usually asymptomatic, since they are insulated from trauma<sup>13</sup>; hematomas are first seen when the child becomes active, and hemarthroses seldom develop until he begins to walk. Occasionally evidence of this disorder is not seen until the patient reaches teenage or young adult life.<sup>93</sup> Spontaneous hemorrhage may be cyclic in nature. Petechiae, which are characteristic of disorders of platelets and blood vessels, are rare in hemophilia, but have been noted in severely affected patients at the "peak" of an "attack" of bleeding.<sup>49</sup> Hemorrhage from the umbilical cord or stump is unusual, but prolonged bleeding after circumcision brought hemophilia to the attention of the ancient Hebrews. Pulmonary and pleural bleeding are uncommon,<sup>16</sup> although mediastinal and pleural shadows have been noted in roentgenograms, and presumably originate from fresh or old hematomas.<sup>93</sup> Intraocular hemorrhage is uncommon, but bleeding into the orbit and conjunctiva occurs frequently. Spontaneous rupture of the spleen has been reported.<sup>73</sup>

*Intracranial bleeding* has been reported in 2.5 to 7.8% of the patients in various series and tends to occur in younger hemophiliacs, especially in relation to head trauma.<sup>364,365</sup>

Fig 37-3 Roentgenogram showing pseudotumor and destruction of the ilium in a patient with hemophilia B

It is frequently subdural, epidural, or intracerebral in location. Subarachnoid bleeding occurred least commonly in the reported patients but had the best prognosis. Hemorrhage also may develop in the spinal cord or spinal meninges. The overall mortality from intracranial bleeding was 70%<sup>364</sup> in one series, but more recent experience suggests a much more favorable prognosis.<sup>351a,365</sup>

*Hemophilic cysts* are a serious complication and most commonly develop in patients with severe hemophilia A or B. Also known as hemophilic "pseudotumors," such cysts represent gradually expanding blood-filled loculations that apparently originate from hemorrhages into confined subperiosteal, tendinous, or fascial spaces (Fig. 37-3).<sup>41</sup> The osmotic pressure created by breakdown products of blood in such confined spaces may produce further influx of fluid, this, together with recurrent bleeding, explains the cyst's slowly progressive increase in size and its ability to erode contiguous structures. Such cysts most commonly develop in the thigh, and many destroy bone as well as the soft tissues as their size increases. These lesions can be more readily prevented than treated. They usually require radical surgical procedures, eg, extensive resections or amputation. Even with optimal supportive therapy, these procedures

often are unsuccessful and are frequently complicated by infection.

*Wound healing* is often slow in hemophiliacs. This is probably due to continued or intermittent hemorrhage or complicating infection. There is no evidence that factor VIII has any specific role in wound healing, as has been postulated for fibrinogen and factor XIII (page 440).

The *psychologic effects* of hemophilia can be many and severe, and often influence the course of the illness.<sup>7</sup> For example, there may be increased risk-taking as a neurotic response to the disease. At times of emotional stress, spontaneous bleeding has been observed. Parental guilt feelings of both a conscious and unconscious nature are common, and the emotional interaction between carrier mothers and affected males often is abnormal.

### Course and Prognosis

It has often been observed that hemophiliacs improve at or after adolescence.<sup>37,77,313</sup> An analysis of 113 cases in 1937 indicated, however, that the more benign course of older hemophiliacs can be attributed to: (1) death in early life of those having the most severe cases; (2) the passing of the teething period; (3) the onset of the "years of discretion"; and (4) increasing inactivity as the result of permanent joint deformities. In the same study it was calculated that the life expectancy of hemophilic babies was one-twelfth of that of the normal. The greatest number of deaths (23%) were due to exsanguination following surgical procedures.

In recent years, prognosis in severe hemophilia has improved greatly. With proper treatment a nearly normal life span can be expected, and the crippling sequelae of the disease can be minimized.

### Laboratory Diagnosis

Basic hematologic examinations reveal nothing characteristic in hemophilia A. The presence or absence of anemia depends on the severity and frequency of bleeding. Blood regeneration is usually rapid when hemor-

rhage has ceased. Neutrophilia may accompany the bleeding. As in other instances of posthemorrhagic anemia (Chapter 13), the bone marrow reflects the response to blood loss. The megakaryocytes are normal or increased in number.<sup>62</sup>

### Screening Tests

The *partial thromboplastin time* usually is prolonged in hemophilia A (Table 37-4). The results of this test vary, depending on the factor VIII level in the individual patient (Table 37-3), but abnormal results are usually obtained if the factor VIII levels are less than 20 to 25% of normal. The abnormality in the PTT can be normalized by the admixture of the patient's plasma with approximately 20% of normal plasma or another reagent that contains factor VIII (Table 37-4). This "corrective" effect provides the basis for many simple "presumptive" tests for hemophilia A.<sup>61,219</sup> Such qualitative techniques are not as reliable as the TGT, however.

The *bleeding time* may be prolonged and the reaction to the tourniquet test may be positive in an occasional patient with hemophilia.<sup>61</sup> In some patients, these findings appear to be correlated with acute exacerbations of bleeding; in others, they may be attributable to the use of aspirin or to associated platelet dysfunction<sup>167b</sup> (page 1129).

The *platelet count* usually is normal or elevated, and clot retraction is normal. Thrombocytosis may reflect a response to acute or chronic hemorrhage, but in many hemophiliacs it has been found in the absence of significant bleeding. It was suggested that this may represent hemostatic "compensation,"<sup>17</sup> but there is little supporting evidence for this view. Morphologic platelet abnormalities have been reported, but are probably not significant.<sup>126</sup>

### Ancillary Tests

The *coagulation time* of whole blood and the results of tests of *prothrombin consumption* vary, depending on the severity of the factor VIII deficiency (Table 37-3). The

clotting time may be 24 hours or longer, and may show spontaneous irregular variations. It will be normal, however, if the factor VIII level exceeds 1% of normal.<sup>361</sup> One-stage tests of prothrombin consumption are a little more sensitive than the clotting time, but will give normal values if the factor VIII level is above 2 to 4% of normal. With the two-stage technique, normal results are obtained when the factor VIII level is above 1% of normal.<sup>361</sup>

The results of the *thromboplastin generation test (TGT)* may be abnormal, due to deficient function of the adsorbed plasma reagent (page 1057). The finding of such a "plasma defect" together with a normal prothrombin time, which excludes deficiency of factor V, is virtually diagnostic of hemophilia A in a patient with a hereditary disorder (Fig. 33-6, page 1059). The *plasma recalcification time* is greatly prolonged. Like the PTT, the TGT and the recalcification time may be corrected by the addition of various "reagents" containing factor VIII (Table 37-4). The thrombin time and Stypven time are normal.

### Factor VIII Assay

Factor VIII assay is a relatively simple technique, which, because of its importance, is becoming available in an increasingly large number of hospitals. Two-stage,<sup>41 210,265,301</sup> one-stage,<sup>163 426</sup> and micro<sup>108</sup> methods are suitable for diagnosis (page 1061). The one-stage techniques are the most widely used since they are somewhat simpler to perform, but they require a supply of plasma from a known hemophiliac, which may be a disadvantage in small laboratories. Such plasma is available commercially. Artificial substrates have been advocated as substitutes for native factor VIII deficient plasma.<sup>82,120</sup>

There is no stable, generally available reference standard for the assay of factor VIII.<sup>14,210</sup> The most satisfactory standard appears to be a lyophilized preparation of concentrated factor VIII,<sup>14</sup> but lyophilized citrated plasma, which is available commercially, or a pool of frozen citrated plasma

carefully collected from normal subjects serves as well under most circumstances. It must be recognized that the factor VIII assay has a relatively large error even in expert hands, and when borderline values are obtained the assay should always be repeated.

### Differential Diagnosis

The diagnosis of hemophilia A is seldom difficult. This is especially true in the severely affected patient in whom repeated and often serious hemorrhagic manifestations, including characteristic ones such as hemarthrosis, will be clearly apparent early in life. It is noteworthy that hemarthrosis with significant orthopedic disability is rare in coagulation disorders other than hemophilia A and hemophilia B.

In patients with the *milder forms of the disorder*, however, failure to recognize the existence of a disease or to make the correct diagnosis is more likely. In such patients, there may be little spontaneous bleeding, and the family history tends to be vague or negative. As pointed out earlier (Table 37-3) the coagulation time may be normal in such patients. Because the diagnosis of hemophilia is often erroneously equated with a prolonged coagulation time, a normal value may be misleading. It must be emphasized that mildly affected hemophiliacs still are prone to hazardous hemorrhage following trauma or during surgical procedures.<sup>291</sup> Neither the coagulation time nor tests of prothrombin consumption can be relied upon to exclude the possibility of hemophilia. In the mildly affected patient, even the PTT and the TGT may be normal, and specific assays must be carried out to confirm or to exclude the diagnosis of hemophilia.<sup>359</sup>

The results of screening tests (Table 37-4) usually are sufficient to exclude the possibility of *acquired hemorrhagic disorders* associated with serious bleeding. Such disorders are seldom associated with a prolonged PTT and a normal prothrombin time, a combination that strongly suggests a hereditary disorder or an inhibitor (page 1208). Among the *hereditary disorders* characterized by this

combination of findings (hemophilia A, hemophilia B, deficiencies of factors XI and XII), factor XII deficiency can be readily excluded, since it is not associated with bleeding (page 1179). Factor XI deficiency in males may mimic mild hemophilia, and hemophilia B is clinically identical to hemophilia A. Both factor XI deficiency and hemophilia B must be distinguished from hemophilia A in the laboratory; the most useful, generally available test for this purpose is the TGT (Fig. 33-6, page 1059). A definitive diagnosis is of great importance since various concentrates, rather than plasma, are now used in the treatment of these disorders.

Von Willebrand's disease in males may be indistinguishable from mild hemophilia A associated with a prolonged bleeding time, even if the latter abnormality is an inconsistent finding. Confirmatory tests for von Willebrand's disease, as discussed on page 1182, are required to make this distinction.

The bleeding manifestations in hemophilia may simulate a great variety of conditions. However, this has resulted in serious confusion only when the correct diagnosis has not been considered, and appropriate laboratory studies have not been ordered. Thus, a deep hematoma may be mistaken for a suppurative condition and surgical drainage may be attempted. Bleeding into a small joint may produce a clinical and roentgenologic picture suggesting sarcoma<sup>124</sup>; when larger joints are involved, tuberculosis, arthritis, Perthe's disease, or syphilis is simulated. Bleeding elsewhere may suggest local causes, eg, kidney tumor, pulmonary disease, peptic ulcer.

*Intra-abdominal bleeding* raises particularly serious diagnostic and therapeutic problems in hemophilia, even when the hemophilia has been accurately diagnosed. Thus, hemorrhage into the psoas, when on the right side, may simulate acute appendicitis so closely that, in the opinion of many experienced workers, there is no reliable way to differentiate between the two.<sup>41</sup> A retroperitoneal hematoma may be mistaken for an appendiceal abscess. Intraperitoneal hemorrhage and bleeding into and around other viscera may simulate perforating peptic ulcer, bowel obstruction, or

virtually any other acute intra-abdominal condition.

## Hemophilia B

That hemophilia represents at least two different disorders was recognized in 1947.<sup>292</sup> Hemophilia B (Christmas disease, factor IX deficiency, plasma thromboplastin component [PTC] deficiency) was first clearly distinguished from hemophilia A by Aggeler et al in 1952.<sup>6,43,319</sup> Hemophilia A is from four to eight times more common than hemophilia B.<sup>39,274</sup>

### Pathophysiology

Hemophilia B does not represent a true deficiency of factor IX in the usual case. As in hemophilia A, the majority of patients with this disorder have normal plasma levels of factor IX-related antigens that neutralize heterologous antibodies obtained from rabbits.<sup>255</sup> The absence of cross-reacting material has been documented, however, in a few patients with hemophilia B.<sup>340</sup> In this form of the disorder, which has been termed *hemophilia B Leyden*,<sup>407</sup> the clinical manifestations tend to diminish with advancing age in association with a rise in the factor IX level from as low as 1% in childhood to levels of 20% or more in adult life. This remarkable variant of hemophilia B resembles the disorder encountered in the Tenna kindreds.<sup>260</sup>

In another variant of hemophilia B, the prothrombin time is prolonged when performed with bovine brain thromboplastin.<sup>50,179,255</sup> This disorder has been termed *hemophilia Bm*<sup>399</sup> and is characterized by the presence in the plasma of CRM that neutralizes both homologous and heterologous antibodies to factor IX.<sup>75,253</sup> The abnormality of the ox brain prothrombin time is proportional in degree to the plasma level of CRM in both affected males<sup>179,399</sup> and carrier females,<sup>50</sup> and presumably is the result of inhibition of the extrinsic pathway of coagulation by the abnormal analog of factor IX. However, there is little evidence that factor

IX normally is involved in the extrinsic pathway of coagulation (page 425), and the mechanism of this inhibitory effect is obscure.<sup>103</sup> An apparently unrelated inhibitor appeared to be the cause of lifelong factor IX deficiency in one patient.<sup>385</sup>

### Genetic Features

Hemophilia B is inherited as an X-linked recessive trait, but the locus on the X chromosome of the gene controlling factor IX production is remote from that involved with factor VIII biosynthesis.<sup>17,96</sup> Certain differences between the genetic features of the two disorders have been documented. Thus, patients with hemophilia B who do not have a clearcut family history ("spontaneous" cases) are relatively less common,<sup>100,374</sup> and abnormal hemorrhage in heterozygous female carriers is more common than in hemophilia A. In one series of 45 obligatory carriers,<sup>258</sup> the mean factor IX level in the plasma was 33%; 40 of the group had levels below 60%, and in 10 the levels were below 25%. As a consequence, carrier detection is somewhat easier in this disorder than in hemophilia A.<sup>107,406</sup> Factor IX levels below 10% have been documented in only six women, including two with chromosomal abnormalities.<sup>50,267a</sup>

### Clinical Features

Severely affected patients (those with factor IX levels below 2%) are less common in hemophilia B than in hemophilia A,<sup>40</sup> but the clinical manifestations of the two disorders are identical.

### Laboratory Diagnosis

The laboratory diagnosis of hemophilia B involves the same approach (Fig. 33-6, page 1059) and methods as those described above for the recognition of hemophilia A (Table 37-3). The screening tests reveal similar abnormalities in the two disorders, except that the prothrombin time is abnormal in the Bm

variant, when either bovine brain or Thrombotest is employed as the thromboplastin.<sup>399</sup> In an occasional subject, the bleeding time is prolonged.<sup>51</sup>

Hemophilia A may be distinguished from hemophilia B by the thromboplastin generation test; in the latter disorder a "serum" defect is apparent.<sup>262</sup> One-stage<sup>107,109,380</sup> and two-stage<sup>46,57</sup> assays for factor IX employ the same principles as those discussed for factor VIII.<sup>37,109</sup> Methods for preparing an artificial substrate plasma that is deficient in factor IX also have been described.<sup>380</sup>

## Factor XI Deficiency

Factor XI deficiency (plasma thromboplastin antecedent [PTA] deficiency) was first recognized by Rosenthal et al in 1953.<sup>343</sup> This disorder was at first thought to be transmitted as an autosomal dominant trait, with a high degree of penetrance but with variable expression. Later studies suggested that it is transmitted as an incompletely recessive autosomal trait manifested either as a major defect in homozygous individuals with factor XI levels below 20% or as a minor defect in heterozygous individuals with levels ranging from 30 to 65%.<sup>229,321</sup> The incidence of this disorder, compared to that of other hereditary coagulation disorders, varies widely, ranging from 1 to 18% and even more<sup>89</sup> of surveyed cases. This variation may be attributable to a particularly high frequency of the disorder in persons of Jewish extraction.<sup>321</sup>

### Pathophysiology

The pathophysiology of factor XI deficiency is poorly understood. In one study of 10 cases, material that cross-reacted with a heterologous antibody to semipurified factor XI was lacking.<sup>128</sup>

### Clinical Features

The clinical manifestations of factor XI deficiency are milder than those of either

hemophilia A or B. As a rule, spontaneous bleeding is rare, and hemorrhage usually occurs only following trauma or after a surgical procedure. Hemarthrosis is quite uncommon, but delayed bleeding has been a particularly treacherous feature in some of these patients.<sup>343</sup> Hemorrhagic manifestations were absent in two patients.<sup>115,395</sup>

### Laboratory Diagnosis

In the homozygous form of factor XI deficiency,<sup>105</sup> the PTT and the coagulation time of whole blood are prolonged, and prothrombin consumption is deficient. These abnormalities can be corrected by giving small amounts of normal serum or plasma from which the vitamin K-dependent coagulation factors have been absorbed (Table 37-4). The clotting time and PTT may be nearly normal when performed in silicone-coated glassware. The bleeding time rarely is prolonged.<sup>426</sup>

In most patients, factor XI levels in the plasma are in the range of 3 to 15% of normal. More severely affected patients are rare. In persons with the mild form of the disorder, the coagulation time and prothrombin consumption usually are normal; even the PTT often is normal.<sup>89</sup> Abnormalities in the plasma of such mildly affected patients may be abolished by freezing.

Deficient prothrombinase formation in the thromboplastin generation test results from abnormalities of both the serum and plasma reagents. The most clearcut abnormalities are obtained when both reagents are derived from the blood of the patient. Approximately 33% of factor XI is adsorbed from plasma by aluminum hydroxide.<sup>278</sup>

Several quantitative assays for factor XI have been described.<sup>278,320</sup> Artificially deficient substrate plasma<sup>178</sup> has proved useful, but such substrates also are deficient in factor XII and possibly the Fletcher factor as well. The celite eluate test is a relatively cumbersome method for the diagnosis of factor XI deficiency.<sup>281</sup> It would appear that, in the assay of factor XI, totally satisfactory results depend on the availability of fresh plasma from a severely affected patient.<sup>113</sup>

## Disorders of Fibrinogen

### Hereditary Afibrinogenemia

Since hereditary afibrinogenemia was first described by Rabe and Salomon in 1920,<sup>315</sup> more than 60 cases have been reported.<sup>197,423</sup> The disorder is inherited as an autosomal recessive trait. Although siblings have been affected, the disorder has not been documented in consecutive generations of the same family. In some instances, moderate hypofibrinogenemia has been demonstrated in presumed heterozygotes,<sup>225,430</sup> but, in most kindreds, carriers cannot be identified by laboratory means. Parental consanguinity has been present in over 50% of reported kindreds.

### Pathophysiology

Hereditary afibrinogenemia appears to be the result of deficient biosynthesis of fibrinogen. Fibrinogen cannot be identified in the blood of affected patients by means of electrophoretic methods or by precipitation with heat or chemicals, although immunochemical methods have sometimes revealed trace amounts ( $<5$  mg/dl).<sup>143</sup> Platelet-associated fibrinogen also is deficient, an observation that presumably explains the abnormalities of platelet function seen in afibrinogenemia (page 1127). Fibrinolytic activity<sup>12</sup> and the turnover rate of infused fibrinogen<sup>143</sup> are normal in this disorder.

### Clinical Features

The hemorrhagic tendency is present from birth and bleeding from the umbilical cord and following circumcision may be profuse. Other common manifestations include bleeding following slight trauma, subcutaneous hemorrhages, epistaxis, and excessive bleeding during the eruption and loss of deciduous teeth. Wound healing may be defective. Despite the complete incoagulability of the blood, patients with this disorder have enjoyed long periods of freedom from hemorrhage and are likely to have much less disability than those with hemophilia A.<sup>315</sup>

Hemarthroses are uncommon, and, in affected women, menses often are normal.

### Laboratory Diagnosis

In the usual case, the blood is incoagulable. The clotting time, PTT, prothrombin time, and thrombin time are grossly abnormal. The TGT and tests of prothrombin consumption give normal findings. The bleeding time is prolonged in approximately 50% of these patients, and more definitive tests provide evidence of platelet dysfunction in the majority of those affected (page 1127). These abnormalities can be corrected *in vivo* and *in vitro* by small amounts of fibrinogen. Because of the total absence of fibrinogen, the erythrocyte sedimentation rate (page 125) usually is nil in this disorder.

### Hereditary or Constitutional Hypofibrinogenemia

In this poorly defined disorder, plasma fibrinogen levels range from 20 to 100 mg/dl.<sup>313,326,331</sup> Hemorrhage is infrequent and rarely is severe. In contrast to afibrinogenemia, symptoms are seldom seen in infancy, and all affected patients apparently have survived into adult life.<sup>326</sup> Both autosomal dominant<sup>296</sup> and autosomal recessive<sup>221,313</sup> inheritance have been described,<sup>331</sup> and several consecutive generations of a family have been affected. The laboratory findings in hereditary hypofibrinogenemia resemble those already described for hereditary afibrinogenemia (Table 37-4) except that the abnormalities are less marked. Some reports of hypofibrinogenemia in the earlier literature may have represented dysfibrinogenemia<sup>163,195</sup> or possibly heterozygous carriers of afibrinogenemia. There is little information concerning the pathophysiology of the disorder, and its status as a clearcut entity has been questioned.<sup>326</sup>

### The Hereditary Dysfibrinogenemias

The inheritance of a qualitatively abnormal fibrinogen was first clearly documented by

Menaché in 1963 (fibrinogen *Paris I*<sup>252</sup>). Since that time, more than 20 different abnormal fibrinogens have been described,<sup>197,326,328</sup> all designated by the city where they were first recognized. The biochemical studies required to demonstrate that these represent different disorders are lacking in many cases, and it is possible that some reports merely represent new kindreds affected with previously described defects; eg, fibrinogen *Vancouver*<sup>163</sup> may be the same as fibrinogen *Baltimore*.<sup>22</sup>

With one exception,<sup>118</sup> the hereditary dysfibrinogenemias are inherited as incompletely dominant autosomal traits. Where information is available, the plasma of heterozygotes has been found to contain both normal and abnormal fibrinogens.<sup>326,414</sup>

### Pathophysiology

The dysfibrinogenemias are the result of qualitative abnormalities of the fibrinogen molecule. Although only preliminary information is available concerning the pathophysiology of these disorders, thus far three different functional abnormalities have been demonstrated. These involve all three steps in the thrombin-fibrinogen reaction, ie, the enzymatic, polymerization, and stabilization steps (Fig. 10-4, page 424). They are: (1) delayed or disordered release of fibrinopeptides following the enzymatic action of thrombin (eg, fibrinogen *Baltimore*,<sup>22</sup> fibrinogen *Bethesda I*,<sup>155</sup> fibrinogen *Gießen*); (2) delayed or disordered polymerization of fibrin monomers (fibrinogen *Zürich I*<sup>113</sup> and *II*<sup>132</sup>; fibrinogen *Detroit*<sup>242</sup>); and (3) deficient cross-linking of fibrin monomers despite the presence of normal levels of factor XIII (fibrinogen *Oklahoma*<sup>162</sup>). In one kindred, a combination of disordered peptide release and retarded polymerization was demonstrated (fibrinogen *Cleveland II*<sup>328</sup>). In another,<sup>118</sup> the disorder was inherited as an X-linked recessive trait, and abnormally rapid fibrin polymerization was clinically manifested as a thromboembolic diathesis. In fibrinogen *Amsterdam*,<sup>198</sup> the abnormality in fibrin polymerization was not appar-

ent in the absence of an undefined plasma protein.

Differences in the several physicochemical and functional properties of the various abnormal fibrinogens have been demonstrated, eg, electrophoretic and chromatographic behavior, carbohydrate content, fibrin ultrastructure, corrective effects of calcium and protamine on the abnormalities in fibrin polymerization.<sup>197,326,328,412</sup> In fibrinogen *Detroit*, the biochemical defect has been elucidated at a molecular level. An extensive and brilliant investigation of this disorder by Blomback and associates<sup>56</sup> and by Mammen and coworkers<sup>242</sup> has shown the abnormality of the fibrinogen molecule to be the transposition of a single amino acid (serine for arginine on residue  $\approx 19$ ) near the thrombin-binding site on the alpha chain (Fig. 10-1, page 413).

### Clinical Features

The clinical picture of the hereditary dysfibrinogenemias is quite similar regardless of the particular fibrinogen that may be present. The majority of patients are asymptomatic.<sup>196a</sup> A mild hemorrhagic diathesis has been described in some forms,<sup>22,165,242,252</sup> and preliminary observations would suggest that wound dehiscence may be more common in some varieties of dysfibrinogenemia than in other hereditary coagulation disorders.<sup>129,253</sup> The occurrence of thromboembolic complications has been reported in several kindreds.<sup>22,195,348</sup>

### Laboratory Diagnosis

Laboratory studies (Table 37-4) reveal a variable prolongation of the prothrombin and the thrombin times. In some instances, the abnormality in the latter test may be partially corrected by the addition of  $\text{Ca}^{++}$  or protamine to the patients' plasma. Most of the abnormal fibrinogens characterized by slow polymerization act as inhibitors of the normal thrombin-fibrinogen reaction,<sup>326</sup> and in these varieties the abnormal thrombin time may be magnified by diluting the thrombin. The

PTT and the coagulation time usually are normal, but may be variably prolonged. Fibrinogen levels are normal when determined by heat or chemical precipitation techniques, or by immunologic methods, but, because of the slow coagulation of the abnormal fibrinogen, assays of coagulable protein may suggest moderate hypofibrinogenemia. Abnormal thrombelastographic tracings have been reported in patients with fibrinogens *Paris I*, *Cleveland*,<sup>34</sup> *Paris II*,<sup>34</sup> *Detroit*, and *Baltimore*.

*Fetal fibrinogen* is a qualitatively abnormal fibrinogen, and is discussed on page 420.

### Factor XIII Deficiency

Factor XIII deficiency was first recognized by Duckert in 1960.<sup>113</sup> More than 24 cases of this hemorrhagic diathesis have now been reported.<sup>9 123 234,411</sup> In most families, the defect is transmitted as an autosomal recessive trait, and consanguinity has been frequent in the affected families.<sup>161</sup> Transmission on the X-chromosome has been postulated in some kindreds.<sup>330</sup>

### Pathophysiology

Antigenic material related to factor XIII has been demonstrated in the plasma of affected persons,<sup>114,372</sup> with few exceptions.<sup>114,214</sup> However, the concentrations of cross-reacting material were subnormal. These data, which were obtained by methods that measure clot solubility as an index of functional factor XIII, suggest the presence of both a qualitative abnormality and a deficiency of the proenzyme. However, the neutralization of heterologous antibodies to factor XIII by the plasma of affected patients could not be demonstrated when factor XIII was assayed by its ability to catalyze the incorporation of monodansyl cadaverine into casein<sup>114</sup>; in fact, the neutralizing potency of the antiserum appeared to increase following interaction with factor XIII. The reason why this disorder is either "CRM-positive" or "CRM-negative," depending on the method

by which residual factor XIII is determined, is unknown.

### Clinical Features

In factor XIII deficiency, bleeding is often first noted when the umbilical cord separates, and deaths from cord hemorrhage have occurred in a number of instances.<sup>416</sup> Spontaneous hemorrhage is seldom severe, although hemarthrosis has been described. Ecchymoses and hematomas are common, but mucosal bleeding is infrequent. Post-traumatic or postsurgical hemorrhage may be serious, and without treatment may persist for days or weeks. Delayed bleeding is not uncommon. Hemorrhage into the central nervous system has been a serious or lethal complication in several patients with factor XIII deficiency, and is significantly more common in this disorder than in other hereditary coagulation disorders.<sup>416</sup> A high incidence of spontaneous abortion has been reported in affected women.<sup>123,191</sup>

Bleeding from the umbilical cord or stump, post-circumcision bleeding, wound dehiscence, and abnormal scar formation appear to be more common in individuals with factor XIII deficiency or afibrinogenemia, than in those with other hereditary coagulation disorders such as hemophilia A and B.<sup>137</sup> The reason for this is unclear, but it has been suggested, with some experimental support,<sup>21</sup> that factor XIII deficiency and afibrinogenemia result in abnormal or deficient fibroblastic proliferation.

### Laboratory Diagnosis

All the usual tests of coagulation give normal results in persons with factor XIII deficiency. The disorder can be readily demonstrated by clot solubility tests, normal clots being insoluble in 5 M urea or 1% monochloroacetic acid. Various chemical and isotopic techniques<sup>114,231,232,233</sup> are preferable to clot solubility measurements for purposes of quantitative assay of factor XIII.<sup>114</sup> The thrombelastogram characteristically shows

reduced amplitude and a faster decrease than is normally found.<sup>113</sup>

## Hereditary Prothrombin Deficiency

Hereditary hypoprothrombinemia is exceedingly rare; at most, 16 kindreds have been reported.<sup>59-97, 335</sup> The disorder is inherited as an autosomal dominant trait, and is clinically manifested as a relatively mild hemorrhagic diathesis. As with deficiencies of the other vitamin K-dependent coagulation factors, both CRM-positive and CRM-negative variants of hypoprothrombinemia have been described. The CRM-negative form is characterized by a true deficiency of prothrombin and appears to be the more common variety.<sup>140, 203, 209</sup> In the CRM-positive variant,<sup>203, 336</sup> the presence of normal amounts of antigenically competent prothrombin has been demonstrated by quantitative immunoelectrophoresis. In this disorder, termed "*constitutional dysprothrombinemia*,"<sup>338</sup> prothrombin appears to be normally consumed, but does not yield normal amounts of thrombin. Both normal and abnormal prothrombin molecules were present in the plasma of affected persons.<sup>336</sup> In one kindred,<sup>203</sup> prothrombin was activated normally by staphylocoagulase.

The laboratory findings in this disorder are summarized in Table 37-4. The prothrombin level in most patients was approximately 10% of normal. The two-stage method provides the only reliable test for true hypoprothrombinemia, since the one-stage prothrombin time may be nearly normal in some of these patients. The TGT is abnormal in some subjects, a finding that was attributed to deficient activation of factor V by thrombin (page 429).<sup>59</sup> The clotting time of whole blood may be normal or prolonged.

## Factor V Deficiency

Hereditary deficiency of factor V ("*parahemophilia*," *labile factor*, or *proaccelerin deficiency*) is an uncommon disease that was first

described by Owren in 1944.<sup>288</sup> It has been reported from various parts of the world,<sup>131, 218, 222</sup> and is transmitted as an autosomal recessive trait that produces clinical manifestations only in individuals who inherit the defective gene from both parents.<sup>215</sup> Other modes of inheritance have been implicated in an occasional kindred.<sup>351</sup> In the heterozygotes, the levels of factor V in the plasma are approximately half of normal, and the carriers are relatively easy to identify by laboratory studies. That this is generally true of coagulation disorders inherited as autosomal recessive traits is unexplained.<sup>406</sup>

### Pathophysiology

Preliminary data would suggest that the basic pathophysiologic mechanism in this disorder is deficient biosynthesis of factor V. The absence of cross-reacting material in the plasma of patients with this disorder has been demonstrated by antibody neutralization studies employing both naturally occurring homologous antibodies<sup>123</sup> and heterologous rabbit antibodies.<sup>101</sup>

### Clinical Features

The clinical manifestations of the disorder usually are relatively mild, but vary greatly even within the same family. In mildly affected patients, spontaneous epistaxis, easy bruisability, menorrhagia, and excessive bleeding after dental extractions or surgical procedures have been observed. In those who are severely affected, hematomas, spontaneous gingival bleeding, and bleeding into the gastrointestinal tract or central nervous system may occur. The disorder seldom produces bleeding in affected neonates, and has been associated with a high incidence of other congenital abnormalities.<sup>351</sup>

### Laboratory Diagnosis

The usual laboratory features of factor V deficiency are summarized in Table 37-4. The bleeding time has been prolonged in approxi-

mately one third of patients,<sup>287</sup> an observation that remains unexplained. Factor V deficiency is the only disorder in which a prolonged prothrombin time is associated with deficient function of the plasma reagent in the thromboplastin generation test (Fig. 33-6, page 1059). Because of the absorption of significant amounts of factor V by platelets, this abnormality in the TGT may be minimized or even abolished if normal platelets are used as the source of PF-3. The most clearcut abnormalities are obtained when a platelet substitute is used, and when the serum reagent is aged at 37°C for four hours.<sup>18</sup> Specific assays for factor V are based on the prothrombin time and are easy to perform. Good results may be obtained by using aged oxalated or EDTA plasma as a factor V-deficient substrate.<sup>163</sup> Several other suitable artificial substrates have been described.<sup>315</sup>

## Factor VII Deficiency

Factor VII deficiency was first described by Alexander et al<sup>8</sup> under the name of *serum prothrombin conversion accelerator (SPCA) deficiency*. Approximately 70 cases of true factor VII deficiency have now been reported.<sup>159,244,287</sup> Also known as *stable factor* or *proconvertin deficiency*, the condition is inherited as an autosomal recessive trait that produces severe deficiency in the homozygote and moderate deficiency, usually without clinical manifestations, in the heterozygote.

Because of the rarity of this disorder, data concerning its pathophysiology are scanty. In two patients, antigens presumably related to factor VII were demonstrated in the plasma.<sup>147,306</sup> However, in most other patients with this disorder, such antigenically competent factor VII appeared to be lacking.<sup>101,244</sup> These preliminary studies suggest the existence of both qualitative and quantitative forms of factor VII deficiency.

Hemorrhage is relatively more severe in patients with factor VII deficiency than in those with deficiency of factor V. Common manifestations include spontaneous epistaxes,

deep subcutaneous hematomas, genitourinary and gastrointestinal bleeding, and hemarthroses. The severity of bleeding following trauma or surgical procedures has varied to a surprising degree in this disorder, and in some instances appeared to bear little relationship to the extent of the laboratory abnormalities.

In factor VII deficiency, normal results are obtained with tests that bypass the extrinsic pathway of coagulation and factor VII (Table 37-4) (Fig. 33-4, page 424), i.e., the prothrombin consumption test, coagulation time, PTT, Stypven time, and thromboplastin generation test.

## Factor X Deficiency

Factor X deficiency was discovered independently by Telfer et al<sup>392</sup> and Hougic et al<sup>180</sup> and is also known by the surnames of the patients who were first found to manifest the defect (*Stuart*<sup>180</sup> and *Prower*<sup>392</sup>). Approximately 20 affected kindreds have since been reported.<sup>228,394</sup> Factor X deficiency is inherited as an autosomal recessive trait, and the genetic features and clinical manifestations of the disorder resemble those of factor VII deficiency, described above.

Several studies employing the techniques of immunodiffusion and antibody neutralization have established the existence of both "CRM-positive" and "CRM-negative" variants of factor X deficiency.<sup>104,307</sup> Significant differences in the laboratory abnormalities encountered in various kindreds further suggest that there are at least two different CRM-positive variants,<sup>104</sup> namely, that present in the Prower kindred<sup>392</sup> in which the Stypven time is abnormal, and factor X *Friuli*<sup>112</sup> in which it is normal. In the CRM-negative variant (the disorder present in the Stuart kindred) the Stypven time also is abnormal.<sup>180</sup> Additional differences in the results of in vitro coagulation tests, the levels of CRM, and immunoelectrophoretic patterns obtained with the plasma of various patients suggest at least two additional variants.<sup>104</sup> Because of the marked polymorphism

of this rare trait, the term *factor X defect* has been proposed.<sup>101</sup>

The laboratory findings in factor X deficiency differ from those in factor VII deficiency in that the thromboplastin generation test reveals a "serum defect." Prolongation of the Stypven time is characteristic in the Stuart and Prower variants (Table 37-4). Prolonged bleeding time has been reported in association with factor X deficiency.<sup>61</sup>

## Factor XII Deficiency

*Factor XII deficiency was discovered by* Ratnoff and Colopy during a routine preoperative measurement of the coagulation time of Mr. John Hageman, an adult who had no evidence or history of abnormal bleeding.<sup>329</sup> The disorder, subsequently named *Hageman factor deficiency*, is relatively rare, and is inherited as an autosomal recessive trait.<sup>19,106,321</sup> In one kindred the inheritance appeared to be autosomal dominant.<sup>28</sup> Chromosomal abnormalities were associated with factor XII deficiency in one patient.<sup>98</sup>

### Pathophysiology

The plasma of patients with factor XII deficiency does not contain material that reacts with antibodies to this factor, as judged by antibody neutralization, hemagglutination inhibition, and immunodiffusion.<sup>370</sup> This preliminary evidence would suggest that this disorder is due to deficient biosynthesis of factor XII.

### Clinical Features

Factor XII deficiency is usually not associated with hemorrhagic manifestations,<sup>329</sup> although minor bleeding has been reported in several of these patients.<sup>45,106,158</sup> It is noteworthy that myocardial infarction and thrombophlebitis have been observed in patients with severe factor XII deficiency,<sup>144,174</sup> and that Mr. Hageman died of thromboembolic complications.<sup>333</sup>

### Laboratory Diagnosis

The coagulant effects of contact activation are diminished or absent in plasma from subjects with factor XII deficiency.<sup>278</sup> The usual laboratory findings (Table 37-4) include prolonged coagulation time, markedly decreased prothrombin consumption, and deficient activity of both the serum and plasma reagents in the thromboplastin generation test (Fig. 33-6, page 1059). Normal levels of factor XII range from as low as 30%<sup>189</sup> to as high as 225%<sup>324</sup> of standard normal plasma. As with factor XI, accurate assays of factor XII depend on a source of fresh substrate plasma from a deficient patient. Laboratory demonstration of the heterozygous state is difficult.<sup>79</sup> The mean level of factor XII in the plasma of carriers is approximately 50% of normal, but observed values were distributed in a bimodal manner, an observation interpreted to suggest the presence of multiple abnormal alleles.<sup>205,406</sup>

The marked discrepancy between in vitro evidence of grossly abnormal blood coagulation and the absence of hemorrhagic manifestations in factor XII deficiency poses fundamental questions regarding the role of coagulation in hemostasis and the significance of laboratory measurements of coagulation. These questions cannot be answered at the present time, although various hypotheses have been formulated; these are discussed on page 438. For practical purposes, factor XII deficiency remains a laboratory curiosity.

## von Willebrand's Disease

The confusion that has surrounded the pathogenesis of von Willebrand's disease is apparent from the many names that have been applied to this disorder. These designations include *angiohemophilia*, *vascular hemophilia*, *pseudohemophilia*, *constitutional thrombopathy*, and "idiopathic" prolonged bleeding time. The disorder was first recognized by von Willebrand in a study of the inhabitants of the Åland islands, and is characterized by a prolonged bleeding time, mild to moderate

factor VIII deficiency, and mild mucocutaneous hemorrhage.<sup>63,223</sup>

## Genetics

There is now general agreement that von Willebrand's disease usually is inherited as an incompletely dominant autosomal trait.<sup>194</sup> The expressivity of this genetic abnormality is, however, highly variable, even among members of a single kindred.<sup>132-234</sup> A family history atypical of an autosomal dominant trait is not uncommonly obtained in von Willebrand's disease, and, in some kindreds, the disorder appeared to be transmitted on the X chromosome.<sup>173</sup> It is not improbable that several genetic abnormalities may underlie this disorder.<sup>63,401a</sup>

## Pathophysiology

### Prolonged Bleeding Time

Prior to the present decade it was thought that the abnormality in primary hemostasis was the result of either a primary vascular defect<sup>238</sup> or an intrinsic abnormality of the platelets.<sup>422</sup> Neither of these hypotheses has found significant support.

Most studies of platelet function have yielded normal results in patients with von Willebrand's disease. These have included measurements of platelet adhesion to collagen, the subsequent release reaction, and aggregation induced by ADP, collagen, and other substances.<sup>223-421,422</sup> Furthermore, transfusion of normal platelets does not shorten the bleeding time in this disorder.<sup>271</sup> Deficient platelet adhesion to the endothelial basement membrane,<sup>201,395a</sup> certain ultrastructural abnormalities of the platelets,<sup>64</sup> and a paradoxical increase in the optical density of platelet-rich plasma mixed with low concentrations of ADP<sup>223,402</sup> have been reported in a few patients. The significance of these observations remains uncertain.

More consistently, two abnormalities have been demonstrated; ie, platelets of affected persons are not retained normally in glass-

bead columns, and those of some patients do not aggregate in the presence of the drug ristocetin.<sup>181</sup> There is good evidence that these abnormalities and the prolonged bleeding time are due to the deficiency of a humoral factor, which, for lack of a better name, is usually termed the "anti-bleeding factor." This factor appears to be an antigenically competent fragment or subunit of the factor VIII molecule (*factor VIII related antigen* or CRM). Materials rich in this substance correct in vitro abnormalities in platelet retention<sup>60,256,422a</sup> and ristocetin-induced platelet aggregation<sup>422b,422c</sup> in the blood of patients with von Willebrand's disease. Plasma levels of factor VIII related antigen are unrelated to the levels of coagulant factor VIII,<sup>422b</sup> since similar results are obtained both in vivo and in vitro with "factor VIII" that has been concentrated or purified from hemophilic plasma.<sup>30,254</sup> However, a consistent correlation between factor VIII levels and the bleeding time has not been clearly established in all cases.<sup>329,329a</sup>

### Factor VIII Deficiency

In most patients with von Willebrand's disease the infusion of normal plasma produces a gradual and sustained rise in the coagulant factor VIII levels of the recipient, which reach a plateau 6 to 20 hours later and may persist for 48 to 72 hours<sup>272</sup> (Fig. 37-4). The factor VIII levels attained cannot be attributed to factor VIII present in the infused plasma, since comparable results are obtained with plasma deficient in factor VIII and with normal serum. In contrast, in patients with hemophilia A, the in vivo effect of a comparable amount of normal plasma is maximal immediately after infusion, but rapidly diminishes at a rate consistent with the short in vivo survival time of factor VIII (Fig. 37-4). This phenomenon, termed "*new factor VIII synthesis*" or "*in vivo complementation*," is presumably the result of the administration of a humoral factor ("*factor VIII-inducing substance*")<sup>263,362</sup> The phenomenon is not reciprocal; ie, the infusion of

plasma from a patient with von Willebrand's disease into a hemophiliac does not produce new factor VIII synthesis.<sup>154</sup> The factor VIII "newly synthesized" in transfused patients with von Willebrand's disease appears to differ immunologically from both the factor VIII present prior to transfusion, and that present in normal subjects.<sup>30,305a</sup>

The phenomenon of new factor VIII synthesis provides clear evidence that at least two genetic loci are involved in the regulation of factor VIII biosynthesis, i.e., (1) the locus on the X chromosome which is abnormal in classical hemophilia and codes the synthesis of normal amounts of functionally defective factor VIII; and (2) a locus on an autosome, which, being abnormal in von Willebrand's disease, results in deficient factor VIII synthesis. The possible identity of, or relationship between, the "anti-bleeding factor" and the "factor VIII-inducing substance" is unclear. In the few kindreds in whom adequate data are available, persons homozygous for the autosomal gene appear to have lower factor VIII levels than do the heterozygotes.<sup>153</sup> They also have more severe bleeding manifestations, and synthesize less "new" factor VIII following plasma infusions. These observations favor the view that the autosomal gene is concerned with production of either a subunit or a precursor of factor VIII<sup>153</sup> and is not merely a regulatory gene.<sup>153</sup>

An immunologic study of 77 patients with von Willebrand's disease demonstrated two distinct groups of patients.<sup>176</sup> In one group, comprised of approximately 75% of the patients, the amount of immunologically reactive factor VIII was proportional to the concentration of functional factor VIII.<sup>176</sup> The factor VIII deficiency in these patients thus is due to deficient biosynthesis of this protein, in contrast to the usual situation in hemophilia A.<sup>432</sup> In another group, consisting of approximately 25% of the patients, factor VIII related antigen was present in normal amounts, but appeared to be qualitatively abnormal.<sup>211a,393a</sup> In these patients, the disorder appeared to be inherited as an X-linked recessive trait, platelet retention as deter-

Fig 37-4. The phenomenon of "new" factor VIII synthesis. Cross transfusion of plasma from patients with classical hemophilia and von Willebrand's disease. The open circles represent the changes in the plasma factor VIII levels of a patient with von Willebrand's disease, following the infusion of 550 ml of plasma from a patient with severe hemophilia A. A significant and sustained increase in the factor VIII levels of the recipient was observed even though no active factor VIII was present in the infused plasma. The solid circles represent the effects of infusing 550 ml of plasma from a patient with von Willebrand's disease into a patient with severe hemophilia A. The factor VIII level in the infused plasma was 15% of normal. Note the slight and transitory effects. (From Shulman et al.,<sup>352</sup> courtesy of the authors and the *Annals of Internal Medicine*.)

mined by the Salzman method was normal, and the phenomenon of "new factor VIII synthesis" could not be demonstrated.<sup>176</sup>

Studies of ristocetin-induced platelet aggregation also suggested the presence of three different groups of patients with von Willebrand's disease.<sup>123a</sup>

Following transfusion of factor VIII into patients with hemophilia A, antigenically competent CRM persists in the circulation long after functionally active factor VIII has disappeared.<sup>26</sup> In von Willebrand's disease, essentially the reverse is found; i.e., antigenically recognizable factor VIII disappears rapidly, whereas coagulant activity remains for 24 to 48 hours.<sup>30</sup> These observations, together with the *in vitro* experiments discussed above, suggest that the major antigenic determinant of factor VIII is located on a portion of the molecule or molecular system that is dissociable, both *in vivo* and *in vitro*, from that portion which bears the site that

functions in coagulation; and, further, that in hemophilia A these two subunits or fragments are synthesized and metabolized in a manner distinctly different from that characteristic of von Willebrand's disease.<sup>27,30,328,372</sup>

### Incidence

Accurate figures concerning the incidence of von Willebrand's disease are lacking, owing to the inadequacy of available diagnostic criteria and the frequency of unrecognized mild or partial forms of the disorder. In many areas this disorder is second only to hemophilia A in frequency, and in some it appears to be the most common of all the hereditary coagulation disorders.

### Clinical Picture

The bleeding manifestations in von Willebrand's disease are consistent with the "hybrid" nature of the disorder. Thus, although the clinical picture is dominated by cutaneous and mucosal bleeding, hemarthroses<sup>105a</sup> and dissecting intramuscular hematomas may develop in the severely affected patient. As in mild classical hemophilia, serious hemorrhage due to traumatic injuries or following surgical procedures is a significant hazard.<sup>223</sup> Petechiae are rare, but gastrointestinal bleeding, epistaxis, and menorrhagia are particularly common. The bleeding manifestations in the usual patient with von Willebrand's disease are relatively mild, however, and patients with the partial forms may be virtually asymptomatic. It has been suggested that the disorder may decrease in severity with advancing age.<sup>223</sup> It definitely becomes milder during pregnancy, when the factor VIII level rises significantly.<sup>27</sup>

### Laboratory Diagnosis

Criteria for the laboratory diagnosis of von Willebrand's disease are, as yet, unsatisfactory.<sup>63 223,422</sup> Of the simpler tests (Table 37-4), both the bleeding time and the PTT may be abnormal. The abnormality in the PTT reflects a slight to moderate reduction

in factor VIII. Plasma factor VIII levels vary greatly. In most patients they range from 5 to 15% of normal,<sup>223</sup> but values up to 30% are not uncommon; rarely, they may be as low as 2 to 3% of normal. The coagulation time and the results of the prothrombin consumption test are normal, unless the factor VIII deficiency is unusually severe.

The Ivy bleeding time, or technical modifications thereof (page 1049), may be more sensitive than the Duke (earlobe) method in detecting the abnormality characteristic of von Willebrand's disease.<sup>422</sup> A method that attempts to quantify both the amount of blood lost and the duration of bleeding may be even more sensitive.<sup>390</sup>

Most methods for the determination of platelet adhesiveness to glass actually measure the retention of platelets within glass-bead columns (platelet retention). Among the numerous methods that have been described (page 1053),<sup>164,390,422</sup> the method of Salzman<sup>117</sup> is the most widely used, and in some hands has provided a valuable ancillary diagnostic criterion for von Willebrand's disease. Deficient retention has been demonstrated in from 80% to as high as 100% of cases,<sup>223</sup> and in many instances this test gave abnormal findings when the bleeding time and factor VIII levels were normal or equivocal. Other investigators<sup>4,164</sup> have obtained less consistent results. A major criticism of the technique has been the unusually wide range of results that may be obtained in the normal population.<sup>422</sup> The consistency of the method may be improved by several technical modifications,<sup>165</sup> and more reproducible results may be obtained with related methods employing heparinized platelet-rich plasma. The latter methods, however, are greatly affected by *in vitro* platelet manipulation.<sup>433</sup>

In mildly affected patients, the administration of small doses of aspirin appears to prolong the earlobe bleeding time (Duke's method). This phenomenon, the so-called *aspirin tolerance test*,<sup>312</sup> has been proposed as an adjunct for the diagnosis of von Willebrand's disease. The specificity of the technique may be seriously questioned<sup>20,422</sup> (page 1021). *Tests of ristocetin-induced platelet ag-*

gregation may be the most sensitive method of detecting mild von Willebrand's disease,<sup>422b,422c</sup> but have not as yet been thoroughly evaluated.

In von Willebrand's disease, one or more of the several abnormalities detected by laboratory means is frequently lacking, and, when present, may fluctuate from time to time.<sup>63</sup> In some patients, this may be the result of exogenous factors, eg, pregnancy, oral contraceptives, exercise,<sup>192</sup> or trauma, all of which have been shown to increase factor VIII levels in this disorder.<sup>117</sup> In many other patients, however, the cause is obscure. Even with the more elaborate confirmatory tests now available the diagnosis of this disorder may be difficult and may require repeated observations over a period of time.

## Miscellaneous Hereditary Coagulation Disorders

Several hemorrhagic disorders,<sup>293</sup> in addition to those described above, have been attributed to hereditary deficiencies of coagulation factors.<sup>78,85,88,342,353</sup> In most cases, their status as specific coagulation disorders is uncertain. Deficiency of *Carr factor*<sup>83</sup> refers to a mild hemorrhagic diathesis that affected several members of a single kindred. The disorder was present in both men and women. *Fletcher factor deficiency*<sup>166,167</sup> is a disorder characterized by abnormally slow contact activation. The PTT is normalized by prolonged incubation in systems containing particulate silicate.<sup>1</sup> Like Factor XII deficiency it is not associated with abnormal bleeding. It has been shown to be due to deficiency of prekallikrein.<sup>429a</sup> The genetics of both of these disorders are unclear.

The *Dyma abnormality* refers to a mild lifelong hemorrhagic diathesis that is inherited as an autosomal recessive trait. It has been described in only a single kindred.<sup>293</sup>

Of unusual interest are reports concerning the presence of combined deficiencies of two or more coagulation factors (Table 37-2). The most common of these appear to be deficiency of factors V and VIII,<sup>352,370a</sup> deficiency of factors VIII and IX,<sup>419,341,368</sup> and

combined deficiency of various vitamin K-dependent factors.<sup>134,220,284,411</sup> Several other combined coagulation defects have been described<sup>133,274,283,350,352</sup> (Table 37-2). Genetic details are lacking in most reports, and some of the reports are not entirely convincing.<sup>150</sup>

## Hereditary Coagulation Disorders in Lower Animals

Hemophilia A has been found in several breeds of dogs, and differs from the human disease in that cross-reacting material is not present in the plasma.<sup>420</sup> Both a clinically severe<sup>71,151</sup> form in Irish setters and a mild form in beagles<sup>76</sup> have been described. Hemophilia A also has been reported in a horse.<sup>279</sup> A bleeding disorder in swine closely resembles von Willebrand's disease in man, but its mode of inheritance is autosomal recessive rather than dominant.<sup>74</sup> In contrast to the human disorder, no unusual bleeding has been observed in canine factor VII deficiency<sup>264</sup> (Table 37-2).

## Therapy of the Hereditary Coagulation Disorders

Various styptics, drugs, diets, and hormones have periodically been advocated for the treatment of the hereditary coagulation disorders. These include "ovarian substance,"<sup>49,382</sup> oral contraceptives,<sup>22a</sup> vitamin K, rutin, bioflavonoids,<sup>811</sup> and peanuts or extracts thereof,<sup>196,405,410</sup> as well as splenic transplantation<sup>167a</sup> (page 417). None of these remedies is of proven value. Topical hemostatics may be of temporary value in small injuries, and certain other measures, to be discussed below, may prove to have some adjunctive value under specific circumstances, eg, hypnosis, corticosteroids,<sup>23</sup> inhibitors of fibrinolysis.<sup>151</sup> However, the only firmly established mode of treatment for the hereditary coagulation disorders is replacement therapy, ie, the intravenous administration of the required factor in the form of blood or blood products derived from normal persons or animals.<sup>55,323,337,339,359</sup>

Table 37.5. Biodynamic Properties of Coagulation Factors of Concern in Replacement Therapy

Disorder	Hemostatic Level (% of normal) (1)	Initial <i>In Vivo</i> Recovery (% of Infused Material) (2)	In Vivo "Survival" of Infused Coagulation Factors	
			First Phase Diffusion "Half- Life" (Hours) (3)	Second Phase Biologic "Half- Life" (Hours) (4)
Hemophilia A (factor VIII deficiency)	25-30	50-80	4-6	12
Hemophilia B (factor IX deficiency)	15-25	25-50	2-3	24
Fibrinogen deficiency	100 mg/dl	50	12	77-106
Prothrombin deficiency	720-40	50-100	8	72-96
Factor V deficiency	15-25	750-100	.	712-38
Factor VII deficiency	5-10	7100	0.5	5
Factor X deficiency	10-20	50-100	2-9	24-60
Factor XI deficiency	710	~100	.	748-84
Factor XIII deficiency	2-3	50-100	.	72-96

Values indicated for hemostatic levels represent the upper limits of published figures

Question marks indicate insufficient data or significant disagreement among published figures

\*In most patients survival curve is monophasic and lacks an initial component

### Replacement Therapy

The objective of replacement therapy is to obtain a concentration of the required factor in the bleeding site such that coagulation may become hemostatically effective.<sup>239</sup> Its achievement involves a consideration of several biodynamic properties of the various coagulation factors (Table 37-5), a general knowledge of the available therapeutic materials, and clinical assessment of the severity of the hemorrhagic manifestations.

### Hemostatic Levels

The hemostatic level may be defined as the lowest plasma concentration of a given coagulation factor that is required for normal hemostasis (Table 37-5, column 1). This value has been determined by purely empirical means, i.e., by measurement of the blood levels of the deficient factor at which bleeding appeared to stop in patients with one of the hereditary coagulation disorders during the course of replacement therapy. Needless to say, such estimates are very inaccurate. In patients with hemophilia A, the hemostatic level of factor VIII is approximately 25 to

30% of normal<sup>239</sup>; in those with hemophilia B, values from 15 to 25% of normal have been reported. Plasma levels of factor XIII as low as 2 to 3% of normal are adequate for normal hemostasis.<sup>359</sup>

### In Vivo Recovery and Survival of Infused Coagulation Factors

When a coagulation factor is infused intravenously into a recipient deficient in that factor, the levels present in the circulation after intravascular mixing are significantly lower than those that would be expected merely from dilution in the recipient's plasma. That this initial *in vivo* recovery of infused coagulation factors (Table 37-5, column 2) is usually less than 100% presumably is due to loss of these proteins into intravascular spaces. The adsorption of coagulation factors by platelets, various cells, vascular surfaces, and, in the case of factor VIII, "sequestration" in the spleen also may be involved. The initial recovery of infused coagulation factors is difficult to quantify, and ranges from nearly 100% recovery of factor XI to as low as 30%<sup>131</sup> of factor IX.

After *in vivo* mixing is complete, the activity of most coagulation factors in the plasma declines in a biphasic manner; i.e., an initial rapid loss of activity is followed by a more gradual decline. The *first or rapid phase* presumably is the result of diffusion into extravascular pools.<sup>359</sup> This "diffusion half-life" (Table 37-5, column 3) ranges from minutes for factor VII, to several hours for factor VIII. In general, it is the rapidity of this first phase, together with the initial *in vivo* recovery of the particular factor, that determines the necessity for and the size of the preliminary or "loading" dose of therapeutic material.

The *second or slow phase* of the survival curve presumably is the result of degradation and reflects the true biologic half-life of the infused factor (Table 37-5, column 4). This parameter, together with the hemostatic level for the factor of concern, is the main determinant of the frequency of administration and the size of the maintenance dose of therapeutic material. For example, approximately 80% of factor VIII infused in the form of *fresh frozen plasma is initially recovered in the circulation; its initial ("diffusion") and subsequent ("biologic") half-lives are approximately 6 and 12 hours, respectively.*<sup>359</sup> Thus, in the treatment of patients with hemophilia A, a modest loading dose is usually employed, and maintenance doses are administered every 8 to 12 hours. In patients with hemophilia B, the initial recovery of factor IX is 50% or less<sup>11</sup>; its initial and subsequent half-lives are approximately 3 and 24 hours, respectively. Hence a very large loading dose is essential, but only small and infrequent maintenance doses are required.

After a large loading dose, or after several courses of therapeutic material have been administered, the "survival curves" of infused coagulation factors become nearly monophasic, presumably because extravascular spaces and the other mechanisms that remove infused therapeutic material from the circulation have become "saturated." With some factors, such monophasic curves are characteristic, e.g., factor XI, and, in some patients, factor V.<sup>418</sup>

## Therapeutic Materials

Prior to 1960, plasma was the only agent generally available for the treatment of the hereditary coagulation disorders. Several concentrated blood products are now available for this purpose. The activity of the various coagulation factors in such concentrates is expressed in terms of units. One such unit is defined as that activity present in 1 ml of fresh plasma from normal male donors. The concentration of all coagulation factors in native plasma is thus 1 unit/ml; levels in bank plasma are 0.8 U/ml because of the dilution with anticoagulant. The potency or extent of purification of various preparations of coagulation factors usually is expressed in terms of the ratio of coagulant activity (per unit weight of protein) in the concentrate to that in plasma.<sup>337</sup>

## Plasma

Rapid losses of factors V and VIII are observed in plasma anticoagulated with EDTA or oxalate. These factors also are lost in stored citrated plasma, but at a slower and more variable rate.<sup>318,378</sup> Consequently fresh or frozen plasma is preferable for treatment of patients with hemophilia A and of those with factor V deficiency. Stored plasma, outdated plasma, and supernatant plasma after removal of the cryoprecipitate contain essentially normal levels of prothrombin, fibrinogen, and factors VII, IX, X, XI, and XIII. Such plasma is suitable for replacement therapy in persons with disorders due to deficiency or abnormality of these substances.

Both the rate of administration, and the total dose of plasma that can be given are limited by the possibility of acute or chronic circulatory overload. The volume expansion resulting from even moderate doses of plasma also limits the blood levels that can be attained. As a consequence, therapy with plasma alone cannot be expected to increase the levels of a deficient factor more than 20% above baseline values.<sup>337</sup> When plasma is the only therapeutic agent available, plasmapheresis may be of adjunctive value.<sup>294</sup>

### *Purified or Concentrated Coagulation Factors*

**CRYOPRECIPITATES.** A major advance in the therapy of hemophilia A was the demonstration by Pool and her coworkers that cold insoluble material obtained from plasma contains high concentrations of factor VIII and fibrinogen.<sup>170-303</sup> This cryoprecipitate, which for many years was discarded during "clarification" of plasma, is prepared by slowly thawing rapidly frozen plasma at 2 to 4°C and then harvesting the precipitate by centrifugation. Cryoprecipitate prepared from 200 ml of fresh plasma contains from 50 to 120 units of factor VIII, approximately 250 mg of fibrinogen, and therapeutically useful amounts of factor XIII, as well as the "factor VIII-inducing substance" that is deficient in von Willebrand's disease. Cryoprecipitation provides 7 to 20 times purification of factor VIII with respect to plasma, and can be carried out by means of a closed double-bag system even in small routine blood banks without special equipment. Because of its simplicity it has proved to be a particularly valuable method of concentrating factor VIII.

**PURIFIED FACTOR VIII.** Among the many methods that have been developed to purify factor VIII (page 417), several have proved suitable for the large-scale production of concentrates of the human factor for therapeutic use. The resulting fractions represent from 10- to as high as 400-fold purification of factor VIII with respect to plasma. They are sufficiently potent to attain *in vivo* factor VIII levels as high as 100% in hemophilic patients without significant expansion of the plasma volume.<sup>12,36,55,338</sup> Most of these preparations of factor VIII are standardized and are provided with a predetermined assay of their potency, which is an advantage in the treatment of major bleeding. High-potency concentrates are relatively more convenient to administer than cryoprecipitates or less concentrated preparations of factor VIII. For example, therapeutic doses may be administered by a syringe, which may be a convenience in various home-care or prophylactic

programs to be discussed below. With these important exceptions, however, it is probable that highly concentrated factor VIII offers no significant advantages over cryoprecipitates, except under unusual circumstances in which very high blood levels of this factor are required. A considerable risk of hepatitis attends the use of most concentrated preparations,<sup>415</sup> since they are prepared from large plasma pools. This may be less of a problem with preparations of high purity.<sup>199</sup> The initial recovery of active factor VIII in the circulation appears to vary with the particular preparation,<sup>110,338,371</sup> a minor disadvantage requiring slight adjustment of the dosage for each preparation. The cost per unit of factor VIII is approximately the same whether concentrates or cryoprecipitates are used.

Factor VIII preparations of both high and intermediate potency are available through the American National Red Cross<sup>199</sup> and from commercial sources in the United States<sup>87</sup> and elsewhere.<sup>86</sup> The biochemical methods used to prepare these purified materials, and details concerning their properties, are beyond the scope of this book. Detailed information has been summarized elsewhere.<sup>31,187,199,211,248,366</sup>

**FACTOR VIII OF ANIMAL ORIGIN.** Factor VIII has been purified as much as 1000-fold from porcine or bovine plasma.<sup>31,239</sup> Such preparations are of proven clinical effectiveness, and were particularly valuable in the treatment of patients having major hemorrhage and during surgical procedures when human factor VIII was in limited supply. However, available preparations are antigenic, a drawback that limits their use to a single therapeutic course. Mild thrombocytopenia and other adverse reactions also have been described in the recipient. Heterologous factor VIII apparently is less reactive with acquired antibodies to factor VIII ("circulating anticoagulants") than is the homologous protein,<sup>360</sup> a property that may prove advantageous in the treatment of bleeding due to such antibodies (page 1208). Animal factor VIII is not as yet commercially available in the United States.

"PROTHROMBIN COMPLEX." The four vitamin K-dependent factors (prothrombin and factors VII, IX, and X) are avidly adsorbed by aluminum hydroxide or barium sulfate, and can be readily concentrated by elution therefrom. This simple procedure is the starting point for several methods of preparing therapeutically useful concentrates of these proteins.<sup>110,113,377,397</sup> A preparation containing 60 times the plasma concentrations of all four of these factors is now commercially available.<sup>93</sup> Variable amounts of factor XI also are present in these preparations. Preliminary data would suggest that this concentrate may greatly improve the efficacy of replacement therapy in patients with deficiencies of these factors.<sup>116,173</sup> As with purified factor VIII, this concentrate may be contaminated with the hepatitis virus.

### "Major" and "Minor" Bleeding

For purposes of replacement therapy, the various bleeding manifestations commonly encountered in the hereditary coagulation disorders may be divided into major and minor categories. Although this distinction is relative and somewhat artificial, it has proved helpful clinically.

Manifestations falling into the "minor" category include bleeding associated with uncomplicated hemarthrosis, symptomatic hematomas in noncritical areas and very minor traumatic injuries, as well as such therapeutic procedures as arthrocentesis, dressing changes, and removal of stitches or drains. Small cuts and scratches, superficial ecchymoses, and small hematomas ordinarily require no replacement therapy. Minor bleeding will usually respond to regimens that produce a hemostatic level once or twice in a 24-hour period.

Major bleeding is by definition life-threatening, and includes hematomas in critical locations and bleeding due to traumatic injuries, particularly those in which there is significant external blood loss, and to surgical procedures, including tonsillectomy and the extraction of even a single molar tooth. In the treatment of major bleeding, the *in vivo*

levels of the deficient factor should be continuously maintained above the hemostatic level. In bleeding of a particularly critical nature such as intracranial hemorrhage or for the prevention of excessive bleeding during neurosurgery, it is probable that even higher levels should be maintained.

### Regimens

Although the various considerations that have been discussed in the foregoing paragraphs provide the scientific basis for replacement therapy in patients with hereditary coagulation disorders, it must be recognized that variations in the responses of individual patients are common, and that, to a certain extent, treatment of persons with these disorders must be individualized. This is particularly true for therapy of patients with the very rare disorders, in whom the hemostatic levels and the biodynamic properties of the deficient factors are poorly defined. Thus, the generalizations discussed below, as well as the regimens summarized in Tables 37-6 and 37-7, should be regarded only as a "first approximation" to the therapy of patients with these disorders.

### Hemophilia A

Although it is effective in *minor bleeding*, plasma is now seldom used in the treatment of patients with hemophilia A. Cryoprecipitates are now widely available and are the most generally useful therapeutic material.<sup>367</sup> Both more and less factor VIII than indicated in Table 37-6 have been recommended.<sup>66,94</sup> For most minor bleeding manifestations, treatment for a minimum of three days is required. Regimens employing a single dose of 20 to 30 U factor VIII/kg have been advocated for the management of hemarthrosis, but have not proved uniformly effective.<sup>216</sup> For the removal of sutures, drains and dressing changes, a single dose of 10 to 15 U/kg of factor VIII usually will suffice. In the treatment of minor bleeding, loading doses are not required, and laboratory monitoring of *in vivo* factor VIII levels is unnecessary.

Table 37-6. Replacement Therapy in Hemophilia A and Hemophilia B

Minor Bleeding			Major Bleeding	
	Therapeutic Material	Loading Dose	Maintenance Dose	
<i>Uncomplicated hemarthroses, hematomas in noncritical areas, hematoma dressing changes,* arthrocentesis,* removal of sutures and drains*</i>				
HEMOPHILIA A (Factor VIII deficiency)	Cryoprecipitate	Not required	1.25-1.75 bags/10 kg every 12 hrs for 2-4 days	3.5 bags/10 kg
	Purified factor VIII†	Not required	10-15 U/kg every 12 hrs for 2-4 days	1.75 bags/10 kg every 8 hours for 1-2 days, every 12 hours thereafter
	Fresh or fresh frozen citrated plasma‡	Not required	10-15 ml/kg every 12 hrs for 2-4 days	10-15 U/kg every 8 hours for 1-2 days; every 12 hours thereafter
HEMOPHILIA B (Factor IX deficiency)	Citrated plasma §	30 ml/kg	7 ml/kg every 12 hrs for 2-4 days	15 ml/kg every 8 hours for 1-2 days, every 12 hours thereafter
	Purified "Prothrombin Complex" †	30 U/kg	10 U/kg every 12 hrs for 2-4 days	7 ml/kg every 12 hours
				10 U/kg every 12 hours

\* Single dose of 15 U/kg or equivalent amounts of concentrated material are usually sufficient

† Initial in vivo recovery of active factor varies somewhat depending on particular preparation

‡ Recommended only if other material is not available

§ Stored, outdated plasma, or plasma after removal of cryoprecipitate is adequate

In the therapy of *major bleeding* in patients with hemophilia A, an initial loading dose of factor VIII should always be administered, and sufficient factor VIII must be given frequently enough to assure that the blood level does not fall below 25% for any length of time.<sup>245</sup> Maintenance doses usually are given every 8 or 12 hours, although some saving of therapeutic material is accomplished by more frequent administration. Regimens employing the continuous infusion of factor VIII have been described.<sup>249</sup> Although theoretically sound, such regimens usually are inconvenient and time-consuming. It should be pointed out that the treatment of post-surgical or major traumatic hemorrhage in patients with mild hemophilia A requires very nearly as much therapeutic material as is needed for the severely affected patient.

There is no general agreement concerning the duration of replacement therapy when major bleeding occurs. Therapy has been continued for 10 to 14 days in most hemophiliacs in whom major surgical procedures were carried out successfully. Many investigators administer the full doses indicated in Table 37-6 for 10 days, followed by half doses for four days. The necessity for such protracted therapy has been questioned.<sup>136</sup> Therapy for five to seven days usually suffices following tooth extractions.

Determination in the laboratory of the *in vivo* levels of factor VIII is highly desirable in the treatment of patients having major hemorrhage. The peak level of factor VIII 10 minutes after an infusion of therapeutic material should be approximately 75% if the level is not to fall below 25% on a 12-hour schedule. The use of the PTT or some other one-stage screening test to replace a specific factor VIII assay cannot be recommended, since the results of these tests may be normal at hazardously low levels of factor VIII.<sup>359</sup>

### *Hemophilia B*

Most of the comments concerning the therapy of patients with hemophilia A apply to the treatment of those with hemophilia B. Because of the low initial *in vivo* recovery and the rapid initial disappearance of factor

IX from the circulation, loading doses are recommended even when minor bleeding occurs. In patients with hemophilia B, it is often difficult to attain hemostatic levels with plasma alone,<sup>337</sup> and in general concentrated material is recommended when major hemorrhage is present.<sup>173</sup> If plasma is the only agent available, very large amounts (60 ml/kg) are infused at the maximum tolerated rate.<sup>359</sup> This is followed by smaller doses at 12-hour intervals (Table 37-6).

### *von Willebrand's Disease*

In the usual patient with von Willebrand's disease, bleeding manifestations are mild, and replacement therapy is seldom required. Because of the phenomenon of "new factor VIII synthesis" (page 1181), the daily administration of small amounts of plasma will usually produce hemostatic levels of factor VIII (Table 37-7).<sup>42,359</sup> In the severely affected patient with marked factor VIII deficiency, relatively little "new" factor VIII is synthesized endogenously, and such patients should be managed much like those with hemophilia A<sup>359</sup> (Table 37-7). In some patients with von Willebrand's disease, the severity of bleeding does not appear to be related to the factor VIII level, and presumably is the result of the abnormality in primary hemostasis. There is no effective therapy for this abnormality, and chronic gastrointestinal hemorrhage and menorrhagia, in particular, may be virtually intractable. Although various therapeutic materials will shorten the bleeding time transiently,<sup>42,50,422</sup> this test should not be employed as a monitor of the efficacy of treatment in this disorder.<sup>42</sup>

In the preoperative preparation of patients with von Willebrand's disease, replacement therapy should begin 24 hours before the operation in order that "newly" synthesized factor VIII may raise the factor VIII level endogenously. Some preparations of purified factor VIII contain little "factor VIII-inducing substance," or "anti-bleeding" factor<sup>295</sup>; for this reason, cryoprecipitates or plasma is preferred for the treatment of patients with von Willebrand's disease.

Table 37-7. Replacement Therapy in Miscellaneous Hereditary Coagulation Disorders

Disorder	Therapeutic Material	Loading Dose	Maintenance Dose	References
von Willebrand's Disease	Fresh or fresh frozen plasma*	Not required	10 ml/kg daily	42, 63, 223, 359, 362
	Cryoprecipitate	Not required	1 bag/10 kg daily	
Fibrinogen deficiency	Cryoprecipitate	4 bags/10 kg	1 bag/10 kg every other day	359
	Purified fibrinogen†	100 mg/kg	20 mg/kg every other day	
Prothrombin deficiency	Stored plasma	15 ml/kg	5-10 ml/kg daily	38, 110, 359
	Purified prothrombin complex	20 U/kg	10 U/kg daily	
Factor V deficiency	Fresh or fresh frozen plasma	20 ml/kg	10 ml/kg every 12 hours	251, 345, 352, 359, 418
Factor VII deficiency	Stored plasma‡	10 ml/kg	5 ml/kg every 6-24 hours	110, 172, 244, 359
	Purified prothrombin complex	10 U/kg	10 U/kg every 6-24 hours	
Factor X deficiency	Stored plasma‡	15 ml/kg	10 ml/kg daily	38, 110, 339, 359
	Purified prothrombin complex	15 U/kg	10 U/kg daily	
Factor XI deficiency	Stored plasma‡	10 ml/kg	5 ml/kg daily	177, 280, 343, 359
Factor XIII deficiency	Stored plasma	5 ml/kg every 1-2 weeks	Not required	113, 191, 359

\*Stored plasma contains adequate inducing factor but may be deficient in factor VIII

†Any purified factor VIII preparation or fibrinogen preparation is satisfactory in equivalent concentrations

‡Plasma after removal of cryoprecipitate is satisfactory

### Miscellaneous Disorders

Therapeutic regimens that have been recommended for the treatment of patients having any of the remaining hereditary coagulation disorders are summarized in Table 37-7, and details concerning treatment will be found in the references provided. In persons with factor XI deficiency, major bleeding is exceedingly rare, and small doses of plasma usually have been effective (Table 37-7). Patients with factor V deficiency also usually

respond well to fresh or fresh frozen plasma. The management of major bleeding due to deficiencies of factors VII and X and prothrombin has been greatly facilitated by the development of concentrates of the "prothrombin complex." Persons with factor XIII deficiency may be readily treated even with weekly administration of plasma; in some, such therapy appeared to induce a prolonged rise in *in vivo* levels suggesting "new synthesis" of this factor.<sup>160</sup> There is as yet little information concerning the treatment of patients with dysfibrinogenemia.

## Prophylactic Therapy

The regular administration of therapeutic material with the object of reducing and possibly eliminating spontaneous bleeding manifestations is a theoretically logical approach to the treatment of persons with the hereditary coagulation disorders.<sup>226</sup> Because of the development of concentrated preparations of factor VIII, such maintenance therapy has now become feasible in patients with hemophilia A. The administration of 1500 to 3000 U of factor VIII three to four times a week has significantly reduced the incidence of hemarthrosis.<sup>171, 403</sup> Trials employing smaller or less frequent administration of factor VIII have yielded less dramatic results.<sup>209, 276</sup> The practicality of routine maintenance therapy with such large amounts of factor VIII remains uncertain. Although the expense of these regimens is not a valid argument against their use,<sup>207</sup> the available supply of whole blood may ultimately be a limiting factor.

The concept of prophylactic therapy seems much more applicable to disorders in which the deficient factor has a long *in vivo* half-life. Prophylactic therapy is very effective in patients with factor XIII deficiency,<sup>71</sup> and encouraging results have been obtained in those with hemophilia B.<sup>173</sup> It has yet to be evaluated in the other hereditary coagulation disorders.

## Home-Treatment Programs

It is the general experience that replacement therapy in hemarthrosis is more effective, and subsequent joint damage is minimized, if replacement therapy is begun *immediately* following the onset of symptoms. The availability of factor VIII concentrates that are stable in home refrigerators has led to the development of various "early home-care" programs. Parents are trained to administer the material at the first sign of bleeding.<sup>173, 207, 316</sup> This can be recommended as the initial course of treatment. Individual factors will determine whether or not further treatment needs to be supervised by a physician.<sup>230</sup>

## Special Aspects of Treatment

### Dental Care

Special attention should be given to preventive dental care of patients with coagulation disorders, so as to minimize the complications, expense, and hazards of operative dental procedures. The extraction of even a single tooth requires replacement therapy. Multiple extractions may save time and expense but create a major bleeding hazard.<sup>359, 419</sup> Acrylic splints, orthodontic rubber bands, and other specialized dental techniques markedly reduce the chance of serious postoperative bleeding.<sup>419</sup> The suturing of bleeding tooth sockets following extractions, particularly of the third molar, should be avoided since it may lead to extension of bleeding into the neck. Mandibular block anesthesia has produced similar complications in some patients, but appears to be safe if performed expertly.<sup>419</sup>

It has been claimed that hypnosis<sup>236</sup> and inhibitors of fibrinolysis such as epsilon-aminocaproic acid (EACA) have adjunctive value in the prevention of bleeding that may follow operative dental procedures in patients with either hemophilia A or hemophilia B.<sup>128a, 148, 331, 337, 417</sup> On the basis of available data, these measures cannot be recommended to the exclusion of replacement therapy. Inhibitors of fibrinolysis have *no demonstrable* effect on spontaneous bleeding manifestations in patients with these disorders.<sup>26, 387</sup>

### Hemarthrosis

All patients with hemarthroses should receive adequate replacement therapy, since only in this manner can the permanent disability resulting from repeated bleeding into the joints be minimized.<sup>112, 200</sup> Pain usually is relieved promptly and is a reliable index of the therapeutic response. Supportive therapy includes immobilization and the administration of analgesics. A short course of corticosteroids was of adjunctive value in one series.<sup>216</sup> Although a time-honored procedure, the value of packing the joint in ice is uncertain.

*Arthrocentesis* usually is unnecessary, but may be of significant benefit when the joint is severely distended or when resolution of the hemarthrosis is delayed despite adequate replacement therapy. The effectiveness of this procedure has not been studied systematically, however. Large volumes of blood seldom can be aspirated, but even a small volume may relieve symptoms. If performed, arthrocentesis should be done immediately before the administration of a "covering" dose of factor VIII.<sup>91</sup>

Early but careful *physiotherapy* aimed at restoring full range of motion of the affected joint should be instituted as soon as the acute stage of hemarthrosis has resolved. More energetic physiotherapeutic techniques should be carried out only in conjunction with an adequate course of replacement therapy. Various orthopedic devices that provide additional support for chronically injured joints have proved useful in reducing the frequency of recurrent hemarthrosis, particularly in the knee and ankle joints, eg, Hessler braces, removable bivalve plaster casts.<sup>91</sup> *Synovectomy* has been recommended in the treatment of patients with chronically recurrent hemarthrosis in seriously damaged joints.<sup>386</sup>

### Miscellaneous

*Styptics* such as Gelfoam, Stypten, and bovine topical thrombin may arrest bleeding from readily accessible sites, if the overlying clots are carefully removed and the material is applied directly to the injured tissues.<sup>66</sup> *Epistaxis* often stops spontaneously and usually only conservative treatment is required. Intranasal tamponade, described on page 1149, has proved helpful in managing this complication. *Hematuria*, to the contrary, may be virtually intractable, and in some patients will not respond to even vigorous replacement therapy. In such patients, 20 to 40 mg prednisone, given daily for one week, may stop bleeding.<sup>3,149</sup> The mechanism of this therapeutic effect is obscure. EACA is contraindicated in the treatment of patients having hematuria, since it may produce intrarenal

obstruction with blood clots.<sup>381</sup> *Surgical procedures* in patients with hereditary coagulation disorders carry greater risk than in the general population,<sup>245</sup> even when optimal replacement therapy is administered, and should be avoided if at all possible. Treatment of bleeding in patients with *acquired antibodies* to the various factors is very difficult. This complication occurs most commonly in those with hemophilia A, and is discussed further on page 1208.

*Narcotics* should be used for pain relief only when absolutely necessary, because of the possibility of addiction. *Aspirin* is contraindicated since it may produce gastric erosions and gastrointestinal bleeding, and may also aggravate or provoke hemorrhagic episodes because of its inhibitory effects on platelet function<sup>201</sup> (page 1129).

Profound *psychologic and sociologic problems* often arise in families affected with the hereditary coagulation disorders and their management may constitute an important part of the overall care of the hemophilic patient.<sup>7</sup> Some useful guidelines for *psychiatric, genetic,<sup>212</sup> and occupational<sup>209</sup> counseling* of families affected with hereditary coagulation disorders have been published.<sup>209</sup>

## Acquired Coagulation Disorders

Deficiencies of Vitamin K-Dependent Factors  
Hemorrhagic Disease of the Newborn  
Miscellaneous Causes of Vitamin K Deficiency  
Hepatic Disease  
Pathologic Inhibitors of Coagulation (the Circulating Anticoagulants)  
Specific Inhibitors  
Inhibitors in Lupus Erythematosus  
Miscellaneous  
Diffuse Intravascular Coagulation  
Fibrinogenolysis  
Miscellaneous

**A**BNORMALITIES in blood coagulation may complicate a large variety of disorders (Table 38-1). These acquired coagulation disorders are more complex than the hereditary forms. In contrast to hereditary disorders in which lack of a single factor is characteristic, in the acquired forms deficiency of several factors usually is found and thrombocytopenia, abnormalities in platelet function, abnormal inhibitors of coagulation, and vascular abnormalities are commonly present as well. Because of the "compound" nature of the hemostatic defect, the severity of bleeding correlates poorly with the results of laboratory tests in acquired coagulation disorders, and replacement therapy often is ineffective. With some notable exceptions, however, bleeding usually is less severe than in the hereditary forms and the clinical pic-

ture often is complicated by signs and symptoms of the underlying disease.

### Deficiencies of Vitamin K-Dependent Factors

Prothrombin and factors VII, IX, and X are synthesized in the liver by a process that is dependent on vitamin K (page 414). Deficiencies of these four factors may develop in a variety of disorders in which there is deficient intake or absorption of vitamin K, as well as in disorders that impair the biosynthetic capacity of the liver (Fig. 38-1). Anticoagulant drugs of the coumarin and indanedione groups antagonize the action of vitamin K and produce an identical coagulation abnormality (Chapter 39).

#### Hemorrhagic Disease of the Newborn (HDN)

Hemorrhagic disease of the newborn is the result of vitamin K deficiency in the neonate. Formerly a major cause of bleeding in the newborn,<sup>27</sup> this disorder is now uncommon because of the routine administration of vitamin K at birth.<sup>27</sup> However, it is still encountered in economically deprived populations.

#### Pathophysiology

There is a moderate but significant deficiency of the vitamin K-dependent coagula-

Table 38-1. The Acquired Coagulation Disorders

I Deficiencies of the vitamin K-dependent coagulation factors	
A	Hemorrhagic disease of the newborn
B	Biliary obstruction (gallstones, strictures, fistulas)
C	Malabsorption of vitamin K (sprue, idiopathic steatorrhea, celiac disease, ulcerative colitis, regional enteritis, gastrocolic fistulas, ascariis infestation)
D	Liver disease
E	Drugs
	1 Pharmacologic antagonists of vitamin K (coumarins, indanediones, diphenylhydantoin, salicylates)
	2 Those that alter gut flora (broad-spectrum antibiotics, sulfonamides)
F	Nutritional deficiency
II Inhibitors of coagulation (Circulating anticoagulants)	
A	Specific inhibitors (antibodies to fibrinogen factors V, VIII, IX, XI, XII, and XIII)
B	In systemic lupus erythematosus
C	Miscellaneous
III Accelerated destruction of coagulation factors	
A	Diffuse intravascular coagulation (DIC) (Table 38-3)
B	Fibrinogenolysis (DIC, liver disease, tumors following surgery)
IV Miscellaneous	
A	Liver disease
B	Disorders of the hematopoietic system (paraproteinemias, polycythemia vera, myelofibrosis, lymphomas, leukemia, others)
C	Others (following massive blood transfusion, uremia, amyloidosis, nephrotic syndrome, drugs such as L-asparaginase <sup>22</sup> )

tion factors in the normal newborn (page 420). The plasma levels of these factors normally fall even further during the first two to five days of life, rise again when the infant is seven to fourteen days of age, and attain normal adult levels at about three months of age.<sup>23</sup> This sequence of events normally does not produce bleeding, but in hemorrhagic disease of the newborn the initial fall is accentuated, and the secondary restoration is delayed and incomplete. As a consequence, coagulation abnormalities become marked and bleeding results.

The deficiency of the vitamin K-dependent coagulation factors that is present at birth, as

well as the slow rate at which adult levels are attained, presumably is the result of intrinsic "hepatic immaturity"; neither of these physiologic events is affected by vitamin K administration.<sup>23</sup> On the other hand, the "secondary" fall of these factors at age two to five days is prevented by vitamin K administration and is the result of a transitory "physiologic" deficiency of vitamin K. Factors that further diminish the amount of vitamin K available at this juncture, and those that further impair the synthetic capacity of the liver, predispose to hemorrhagic disease of the newborn. These are: (1) prematurity, (2) inadequate dietary intake, (3) delayed gut colonization by bacteria, and possibly (4) maternal deficiency of vitamin K and (5) various obstetric and perinatal complications.

*Prematurity* has frequently been associated with hemorrhagic disease of the newborn.<sup>1,2,20</sup> Levels of the vitamin K-dependent factors at birth are approximately proportional to gestational age and birth weight.<sup>5</sup> In premature infants, the "physiologic immaturity" of the liver is marked, and the response to the vitamin K that is present is subnormal.

Most factors associated with *deficient intake* of vitamin K also delay the *colonization of the gut* by bacteria. These include delayed feeding, breast feeding, vomiting, severe diarrhea, and antibiotics, including those present in mother's milk. Maternal milk and colostrum are poor sources of vitamin K,<sup>23</sup> and reliance on breast milk as the sole source of nutriment in the neonatal period is an important factor in many cases of hemorrhagic disease of the newborn.<sup>27</sup>

The importance of placental transfer of vitamin K during the antenatal period is uncertain, as is the contributory role of maternal deficiency of this vitamin. Traumatic delivery, especially if it is associated with prolonged hypoxia, and various other obstetric and perinatal complications may predispose to hemorrhagic disease, presumably by impairing hepatic function<sup>3</sup>; the evidence for the importance of these factors is largely circumstantial. Coumarin and indanedione

Fig. 38-1. Causes of deficiencies of the vitamin K-dependent coagulation factors. The origin, absorption, and transport of vitamin K under normal circumstances are illustrated by dashed lines. Processes leading to deficiency of this vitamin are indicated by solid lines. The structures of the K vitamins are shown in the inset.

drugs, as well as diphenylhydantoin,<sup>25a</sup> cross the placenta and may produce hemorrhagic disease in the newborn.<sup>10</sup>

### Clinical and Laboratory Features

Bleeding usually is severe,<sup>30</sup> and commonly first occurs on the second or third day of life.<sup>23</sup> The most common manifestations are melena (melena neonatorum), large cephalohematomas, and bleeding from the umbilical stump and following circumcision. Generalized ecchymoses, often without petechiae,<sup>3,23,30</sup> intracranial bleeding, and large intramuscular hemorrhages also may develop.

*Laboratory diagnosis* is relatively simple (Table 38-2), but the physiologic differences in the results of various coagulation tests in neonates as compared with those at a later age must be kept in mind (page 1067). In infants with hemorrhagic disease of the newborn the prothrombin time always is markedly prolonged and the PTT and the thrombin time also are prolonged; however, the results of these tests may also be abnormal in unaffected neonates (page 1067). The coagulation time of whole blood usually is prolonged in infants with hemorrhagic disease of the newborn, in contrast to most forms of vitamin K deficiency in adults. Specific assays reveal marked deficiencies of prothrombin and of factors VII, IX, and X. Factors V, VIII, and fibrinogen are present in normal amounts. The bleeding time and the platelet count usually are within normal limits.

It should not be assumed that bleeding in the neonate is invariably the result of vitamin K deficiency. In the *differential diagnosis of HDN*, virtually all causes of bleeding, particularly thrombocytopenia (page 1090) and diffuse intravascular coagulation (DIC), must be considered.<sup>7</sup> Various forms of DIC have been referred to by the somewhat confusing term "secondary hemorrhagic disease of the newborn."<sup>1,7,23</sup> The hereditary coagulation disorders (Chapter 37) also may produce serious hemorrhage in the neonatal period. Significant prolongation of the prothrombin time is not found in the most common hereditary disorders, eg, hemophilia A and hemo-

philia B. Umbilical bleeding and hemorrhage following circumcision are relatively less common in the hereditary coagulation disorders than in hemorrhagic disease of the newborn.

### Treatment

Vitamin K<sub>1</sub> (0.5 to 1.0 mg given intravenously) is dramatically effective in the treatment of hemorrhagic disease of the newborn. Shortening of the prothrombin time may be expected within six hours, and normal "neonatal" levels of the four vitamin K-dependent factors usually are attained within 24 hours. In severe cases, two or three doses of vitamin K<sub>1</sub> at four- to eight-hour intervals may be required, and the transfusion of fresh blood may be helpful.<sup>23</sup> Replacement therapy with plasma or concentrates of the vitamin K-dependent factors is quite effective (page 1187), but seldom is necessary. Premature infants usually respond poorly to vitamin K<sub>1</sub>. Larger (2 mg) or repeated (every four to eight hours) doses of vitamin K<sub>1</sub> may be required to counteract the effects of coumarin drugs.<sup>23</sup>

The administration of large doses of vitamin K may produce hemolysis, hyperbilirubinemia, and even kernicterus in the neonate. This appears to be a greater hazard with the synthetic derivatives than with vitamin K<sub>1</sub>, but even the latter may be dangerous in very large doses.<sup>23</sup>

Hemorrhagic disease of the newborn can be prevented by administration of vitamin K *to the mother prior to delivery*. However, most authorities recommend that vitamin K<sub>1</sub> (1 mg, parenterally; 2 mg, orally) be given to the infant. This procedure is now routine in most nurseries.

### Miscellaneous Causes of Vitamin K Deficiency

*Obstruction of the biliary tract*, either intrahepatic or extrahepatic, produces vitamin K deficiency because of the absence of bile salts in the gut. Complete obstruction may lead to severe coagulation abnormalities and bleeding within two to four weeks. This was a major obstacle to surgical procedures on the

biliary tract prior to the discovery of vitamin K.

Most *malabsorption syndromes* and various other chronic gastrointestinal disorders also may give rise to vitamin K deficiency, eg, celiac disease, cystic fibrosis,<sup>37</sup> sprue,<sup>21</sup> gastrocolic fistulas, ulcerative colitis, regional enteritis, extensive gut resections, protracted diarrhea of any cause,<sup>29</sup> ascaris infestations.<sup>3,18,34</sup> Severe abnormalities of coagulation with bleeding are less common in these disorders than in biliary obstruction, presumably because absorption of vitamin K is seldom completely deficient.

Because vitamin K normally is available from two independent sources (Fig. 38-1), neither *nutritional deficiency*<sup>29</sup> nor *gut sterilization* alone produces vitamin K deficiency of a degree that results in significant deficiencies of the vitamin K-dependent coagulation factors.<sup>8</sup> However, when broad-spectrum antibiotics or nonabsorbable sulfonamides are given to patients who are already nutritionally deficient, coagulation abnormalities and bleeding may result.<sup>12,15</sup>

There is indirect evidence that antibiotics, poor diet, or any of the above-mentioned disorders may predispose to coumarin toxicity (page 1245).<sup>16,32</sup>

In adults, the parenteral administration of 10 to 20 mg of vitamin K<sub>1</sub> abolishes coagulation abnormalities within 24 hours if they are the consequence of deficiency of this vitamin. Failure of vitamin K to normalize the prothrombin time is good evidence for the presence of a complicating process, eg, liver disease, DIC. Repeated administration of vitamin K or larger doses may be required to reverse the effects of coumarin toxicity (page 1245), but, with this exception, there is no evidence that large doses of vitamin K are any more effective than those mentioned above. The synthetic vitamins K<sub>3</sub> (menadi-ones) may be absorbed in the absence of bile salts and in various malabsorption syndromes.<sup>8</sup> However, these congeners of vitamin K have a more transient effect than the natural forms of this vitamin,<sup>17</sup> and offer little therapeutic advantage in the usual case.

Vitamin K may produce hemolytic anemia

in patients with hereditary deficiencies of various red cell enzymes (Chapter 23).

## Hepatic Disease

Virtually every hemostatic function may be impaired in patients with severe hepatic disease.<sup>25</sup> This results from deficiencies in both the biosynthetic and clearance functions of the liver. The pathophysiology of some of these abnormalities is discussed elsewhere, namely, thrombocytopenia (page 1098), fibrinogenolysis (page 1224), and the effects of products of fibrinogen catabolism on platelets and on the coagulation mechanism (page 438).

### Pathophysiology

In liver disease, *deficiencies* of prothrombin and factors VII, IX, and X result mainly from synthetic incompetence of the hepatic cells. In addition, in some cases there may also be vitamin K deficiency as the result of poor diet, or mild malabsorption caused by insufficient production of bile salts or exocrine pancreatic insufficiency.<sup>8</sup> Fibrinogen and factor V also are synthesized by the liver, but neither factor is vitamin K-dependent; both may be deficient in severe liver disease. Mild deficiencies of factors XI<sup>24</sup> and XIII<sup>36</sup> also have been reported.

In addition, it is possible that hypervolemia or accelerated catabolism contribute to the deficiencies of coagulation factors in some patients with severe liver disease.<sup>281</sup> The loss of fibrinogen into ascitic fluid may be significant in some patients.

*Endogenous plasminogen activators* normally are removed from the circulation by the liver (page 435). Consequently, in patients with severe liver disease these activators may circulate for an abnormally long time, and may produce a *state of chronic or intermittent fibrinogenolysis*. This may be an important contributory factor in the pathogenesis of hypofibrinogenemia (page 1224). In such patients, surgical procedures or trauma, certain drugs, or electroshock may induce acute fibrinogenolysis.<sup>11</sup>

There is some evidence that the cirrhotic

liver produces an *abnormal plasminogen activator*,<sup>9</sup> and that the levels of circulating antiplasmins may be subnormal in patients with cirrhosis as a consequence of deficient hepatic synthesis.<sup>31</sup> These processes are of uncertain importance in the pathophysiology of fibrinogenolysis in liver disease.<sup>11,22</sup>

The most significant consequence of fibrinogenolysis in liver disease is the *production of large quantities of fibrinogen degradation products (FDP)*, which may persist in the circulation for abnormally long periods because of deficient hepatic clearance. The effects of such FDP presumably underlie the abnormalities of platelet function that have been reported in some patients with hepatic disease.<sup>23</sup> Azotemia is common in terminal liver disease; this abnormality also impairs platelet function (Chapter 35).

Because it is associated with deficient hepatic clearance of activating substances and of products of coagulation, severe liver disease theoretically would predispose to the development of DIC. Fibrinogen catabolism often is accelerated in cirrhosis,<sup>281</sup> and may be normalized in some patients following heparin administration. However, heparin administration seldom decreases the duration or severity of bleeding in patients with severe liver disease.<sup>115</sup> Furthermore, fibrinogen catabolism may be accelerated in patients with extrahepatic obstruction of the portal vein,<sup>281</sup> in whom abnormal bleeding does not occur. Although the question has not been settled, present evidence would suggest that DIC is only rarely responsible for bleeding in patients with severe liver disease in the absence of other etiologic factors, eg, sepsis, shock, cancer.<sup>2</sup> The difficulty of distinguishing between DIC and the effects of severe liver disease by laboratory procedures is discussed on page 1221 (Table 38-2).

### Clinical Picture

In view of the numerous hemostatic abnormalities that may be present, it is surprising that many patients with severe liver disease do not bleed abnormally. Gastrointestinal hemorrhage is the commonest

bleeding manifestation, but it almost always originates from a local lesion, eg, esophageal varices, peptic ulcer, gastritis. The degree to which hemostatic abnormalities contribute to such bleeding is uncertain. In one large series,<sup>6</sup> gastrointestinal bleeding was not significantly more severe or protracted in the presence of coagulation abnormalities, but, in another study, serious hemorrhage occurred only in patients with prolonged prothrombin times and significant factor IX deficiency.<sup>26</sup> Moderate generalized bleeding manifestations, such as recurrent ecchymoses and epistaxis, are not uncommon, and severe generalized bleeding may complicate surgical procedures, including biopsies and other minor procedures. Acute fibrinogenolysis<sup>14</sup> may be the major pathophysiologic factor in such patients, and is particularly hazardous and unpredictable, since it may develop despite normal screening tests of coagulation.

### Laboratory Diagnosis

The laboratory findings in liver disease vary with the cause and severity of the underlying disorder, and range from a slight prolongation of the PTT in anicteric hepatitis to the picture summarized in Table 38-2, which is seen in severe decompensated cirrhosis. In cirrhosis, coagulation abnormalities correlate with the presence of active disease and not with the presence of portal hypertension.<sup>4</sup> Although coagulation abnormalities may be minimal in inactive cirrhosis, thrombocytopenia alone is not uncommon in association with portal hypertension. Fibrinogenolysis is significantly more common in cirrhosis than in acute hepatocellular disease, eg, hepatitis. The plasma levels of factor VIII may be elevated in hepatic disease, and may be very high in the presence of acute hepatocellular necrosis.<sup>9</sup> Coagulation abnormalities are seldom marked in biliary cirrhosis, and hemostatic abnormalities of any sort are rare in metastatic liver disease.<sup>4</sup> The presence of a qualitatively abnormal fibrinogen (acquired dysfibrinogenemia) (page 1174) has been reported in patients with hepatomas.<sup>33,35</sup>

(1) May reveal effects of acute bleeding, or abnormality characteristic of underlying disease

(2) One stage assays may yield aberrant results

(3) Results may differ from adult norms in normal neonates

(4) Hypofibrinogenemia may alter results

(5) Plasminogen depletion may alter results

## Treatment

Vitamin K produces some improvement in the coagulation abnormalities in approximately 30% of patients with liver disease.<sup>26</sup> Large doses of vitamin K may prolong the prothrombin time in some subjects<sup>8</sup>; the explanation of this paradoxical effect is obscure.

Replacement therapy is often disappointing in liver disease.<sup>26</sup> Factors that may explain this include the very short *in vivo* half-life

of factor VII, hypervolemia, and the fact that the *in vivo* recovery of transfused factor IX is significantly lower than that of other factors, even in the absence of liver disease (Table 37-5, page 1184). In general, replacement therapy is indicated only in the presence of serious bleeding, or prior to surgical procedures. Fresh plasma is preferable, but the effects of even maximum doses (15–20 ml/kg of body weight) are often transient.<sup>3</sup>

*Antifibrinolytic agents* may be indicated in patients with fibrinogenolysis. The clinical effects of these drugs are hard to assess<sup>13</sup> in chronic liver disease, but good results have been obtained in the treatment and prevention of acute postsurgical bleeding, particularly that associated with portacaval shunts.<sup>11</sup> Thromboembolic complications have been reported following EACA administration in some patients

## Pathologic Inhibitors of Coagulation

The pathologic inhibitors of coagulation or circulating anticoagulants may be defined as "abnormal endogenous components of blood that inhibit the coagulation of normal blood."<sup>79</sup> They may act at virtually any stage in the process of coagulation. It is now clear that some inhibitors are antibodies, but with this exception the nature and mode of action of these substances are poorly understood.<sup>79</sup>

### Antibodies to Specific Factors

Antibodies to coagulation factors usually act as specific inhibitors; ie, they inactivate a single factor. They produce a clinical and laboratory picture that resembles a hereditary coagulation disorder in many respects. Such antibodies have provided an important new research tool that is of particular value in the study of the qualitatively abnormal forms of the various coagulation factors (page 1160).<sup>73</sup>

### Antibodies to Factor VIII

Antibodies to factor VIII are the most common of the specific inhibitors. They have been demonstrated in from 5<sup>42</sup> to 21%<sup>79,86</sup> of patients with hemophilia A, most commonly in those who are severely affected. Rarely, they complicate mild forms of the disorder.<sup>40,52</sup> Antibodies to factor VIII also arise spontaneously in association with vari-

ous chronic inflammatory diseases such as rheumatoid arthritis, systemic lupus erythematosus, and ulcerative colitis<sup>93</sup>; and in elderly persons in the absence of apparent underlying disease.<sup>96</sup> Less commonly antibodies are found in association with drug reactions,<sup>67</sup> pregnancy and the puerperium,<sup>79,93</sup> and various other disorders.<sup>63</sup>

### Pathophysiology

In patients with hemophilia A, the development of antibodies presumably is related in some way to replacement therapy with factor VIII, but the immunologic mechanism remains unclear.<sup>41</sup> It has been clearly established, however, that, once an antibody has developed in a patient with hemophilia A, administered factor VIII acts as an antigen.<sup>92</sup> The "immunizing events" leading to the development of antibodies of the spontaneous type remain obscure.

Most antibodies to factor VIII are immunoglobulins of the IgG type.<sup>57,93</sup> In one patient with multiple myeloma,<sup>63</sup> an IgA protein acted as an inhibitor of factor VIII, and one inhibitor of the spontaneous type was an IgM immunoglobulin.<sup>51</sup> In some patients, inhibitory activity is present in both the IgG and IgM proteins.<sup>73</sup> In many, the light chains of the antibody appear to be entirely of one type, ie, kappa<sup>93</sup> or lambda.<sup>59</sup> Such "monotypic" antibodies could not be demonstrated by others.<sup>85,96</sup>

These antibodies inactivate factor VIII by means of a time and temperature dependent reaction, the kinetics and stoichiometry of which are quite variable.<sup>43,73,85,93</sup> There is some evidence that antibodies arising in patients with hemophilia A have different kinetic properties than those that form spontaneously.<sup>67</sup> In most subjects, the inactivation of factor VIII is irreversible, but, with antibodies of low affinity, the factor VIII-antibody complex may dissociate in vitro. This phenomenon may produce aberrations in the assay system, and may explain certain puzzling laboratory features in "atypical" cases.<sup>41,45</sup>

## Clinical and Laboratory Features

The *bleeding manifestations* resulting from antibodies to factor VIII are virtually identical to those seen in hemophilia A, and may be severe (page 1164). It is probable that such inhibitors explain some reports of hemophilia in the female. Massive hemorrhage following trivial trauma, spreading hematomas in soft tissues, spontaneous and intractable epistaxis, and even hemarthrosis may occur.<sup>95</sup> When antibodies arise in patients with mild hemophilia A, bleeding typical of severe deficiency may develop.<sup>40</sup> More significantly, the patient may become virtually refractory to replacement therapy. This may have serious and even fatal consequences.<sup>87</sup> In one patient who developed antibodies to factor VIII during pregnancy, the inhibitor crossed the placenta.<sup>60</sup> Rarely, antibodies to factor VIII are associated with thrombocytopenia.<sup>102</sup>

The *laboratory findings* resemble those observed in persons with hemophilia A (Table 38-2). Factor VIII levels usually are nil in severely affected patients but range up to 10% or even higher. Specific tests for antibodies involve the demonstration of progressive and time-dependent inactivation of factor VIII in vitro by the plasma or serum of the patient. Simple mixing techniques based on the PTT, the recalcification time, and the coagulation time have been described<sup>79</sup> (page 1062), and several methods for quantifying the levels of antibody have been devised.<sup>43,87,98,100</sup> An in vivo screening test for antibodies to factor VIII also has been described.<sup>97</sup>

Antibodies to factor VIII do not fix complement.<sup>88</sup> Presumably because the factor VIII-antibody complex is soluble under most conditions, precipitation and immunodiffusion methods usually have yielded negative results. Positive serologic results were obtained with hemagglutination methods in one case.<sup>89</sup>

## Treatment

Huge amounts of factor VIII concentrates (20,000 to 200,000 units) produced apparent

remission of bleeding in some patients,<sup>45,55</sup> but many others have failed to respond. In one series,<sup>85</sup> the effectiveness of factor VIII administration appeared to be determined by the affinity of the antibody for factor VIII. Therapy with factor VIII was seldom successful in patients with high-affinity antibodies and infinite coagulation times.<sup>95</sup> It has been suggested that in such patients the use of factor VIII concentrates of bovine or porcine origin may offer a significant therapeutic advantage, since such heterologous factor VIII is less reactive with most antibodies than is human factor VIII.<sup>98</sup> Continuous slow infusion of factor VIII may be more effective than the usual intermittent regimens, owing to the time-dependent nature of the antibody-factor VIII interaction.<sup>95</sup>

In most patients with hemophilia A who have a factor VIII antibody, infused factor VIII provokes a rapid rise in the titer of antibody.<sup>55,87</sup> Consequently, replacement therapy with factor VIII should be avoided in such patients if at all possible. There is no direct evidence that infusion of factor VIII has a similar effect in patients with inhibitors of the spontaneous type.

With a few exceptions,<sup>94</sup> corticosteroids have proved therapeutically ineffective.<sup>41,79</sup> The adjunctive value of exchange transfusions and immunosuppressive drugs has not been thoroughly evaluated.<sup>92,95</sup> The results of combined therapy with immunosuppressive drugs and massive doses of factor VIII have been encouraging.<sup>55,68</sup> Spontaneous remissions may occur in a significant number of patients, particularly when the antibody developed following penicillin therapy<sup>67</sup> or during pregnancy.<sup>79</sup>

## Miscellaneous Specific Inhibitors

Specific inhibitors that are directed against several other coagulation factors have been well documented. The available evidence suggests that these inhibitors also are antibodies.<sup>56</sup> Inhibitors of factor IX are very rare,<sup>72,82,84</sup> and have been demonstrated only in patients with hemophilia B. In contrast to

antibodies to factor VIII, they act instantaneously. An immunoabsorbent compound has been prepared from one such antibody to factor IX.<sup>82</sup> In one kindred, an inhibitor of factor IX appeared to be the result of an inherited trait.<sup>61</sup> Inhibitors of factor V have developed in several patients.<sup>58,59</sup> In contrast to most other specific inhibitors, they seldom produce serious hemorrhage<sup>56</sup> and disappear spontaneously in most cases. In several patients, the development of inhibitors of factor V was associated with the administration of streptomycin.<sup>56</sup> A precipitating antibody to fibrinogen has been demonstrated in patients with hereditary afibrinogenemia following transfusions.<sup>47,54</sup> Specific inhibitors of factors XI and XII<sup>30,51</sup> and of the activated form of factor XI<sup>49</sup> have been described in association with systemic lupus erythematosus.

Specific inhibitors of factor XIII have been described following transfusions in patients with hereditary deficiencies of this proenzyme<sup>64,77</sup> and in previously normal persons.<sup>66,78,80</sup> Many of the latter had received isoniazid,<sup>74,75</sup> and it was suggested that this drug may alter factor XIII in such a manner that it becomes anigenic.<sup>75</sup> These inhibitors may impair the activation of factor XIII, or may be directed against the cross-linking sites of fibrin.<sup>90</sup>

### Inhibitors in Systemic Lupus Erythematosus

A unique type of coagulation inhibitor is commonly associated with systemic lupus erythematosus. These "lupus anticoagulants" have been detected in from 10 to 15% of patients in several large series.<sup>56</sup> The inhibitor alone seldom produces symptoms and, in most patients in whom bleeding was observed, it appeared to be the result of coexistent thrombocytopenia, uremia, or prothrombin deficiency.<sup>56</sup>

Despite intensive study, the lupus anticoagulants remain poorly understood. They are immunoglobulins of either the IgG or IgM class, but there is little evidence that they are antibodies. They act instantaneously rather than in a time-dependent manner, and, when

a specific reaction is measured, they appear to affect the rate rather than the yield. In some cases, a plasma cofactor apparently is required for their inhibitory action.<sup>103</sup> As a consequence of the foregoing, these inhibitors are very difficult to study, and their mode of action has been variously attributed to inhibition of the interaction between factors V and X,<sup>46</sup> inhibition of the interaction between factors IX and VIII,<sup>44</sup> and antagonism of prothrombinase.<sup>103</sup> Most data favor the last view.<sup>56,83,71,86</sup> There is indirect evidence that the lupus anticoagulants may be directed against the phospholipid moiety of prothrombinase.<sup>56</sup>

The results of laboratory tests (Table 38-2) that employ undiluted blood or plasma, eg, the whole blood coagulation time, thrombin generation test,<sup>44</sup> PTT, may show marked deviation from normal. The effects of the inhibitor often are diminished or abolished by dilution. The prothrombin time usually is prolonged, an abnormality that may be magnified by dilution of the tissue thromboplastin in some cases.<sup>79</sup> The results of the thromboplastin generation test usually are normal except when the patient's plasma is used as substrate. A moderate deficiency of prothrombin has been reported in most cases,<sup>44</sup> but this additional abnormality cannot be clearly related to the presence of the inhibitor. With this exception, the results of specific assays for various coagulation factors usually are normal, although the inhibitor may produce artifactual abnormalities in one-stage assay systems.

Spontaneous remissions are uncommon,<sup>56</sup> but treatment is seldom required. Corticosteroids<sup>79</sup> and immunosuppressive drugs<sup>49</sup> diminish or abolish the coagulation abnormalities in many patients.

### Miscellaneous Inhibitors

Bleeding has been attributed to presence of antithrombins in patients with various disorders, most commonly in those with liver disease. It would now seem that, in most of these patients, such antithrombins were, in fact, FDP and were the result of underlying

intravascular coagulation or fibrinogenolysis. The physiologic antithrombins are discussed on page 431.

In multiple myeloma and other *paraproteinemias*, abnormal proteins may be absorbed by fibrinogen or fibrin. They act as antithrombins and also as inhibitors of fibrin polymerization, and result in gelatinous, structurally abnormal clots.<sup>50,59</sup> The formation of complexes between other coagulation factors and abnormal proteins has been demonstrated *in vitro*.<sup>70</sup> It is difficult to assess the clinical significance of coagulation abnormalities in the paraproteinemias. Laboratory abnormalities seldom correlate closely with the severity of bleeding, and coexistent abnormalities such as hypercoagulability and fibrinolysis,<sup>62,83</sup> thrombocytopenia, platelet dysfunction, and uremia are commonly present.

The presence of large amounts of FDP also may explain some reports of circulating "heparin-like" anticoagulants. In most cases, heparin was implicated merely because protamine reversed the coagulation abnormalities *in vitro*,<sup>79</sup> an effect that can be produced in many disorders in which large amounts of FDP are present in the circulation. It remains uncertain whether heparin in concentrations sufficient to affect coagulation ever is released from endogenous sites in man.

An anticoagulant has been isolated from leukocytes of patients with chronic myelocytic leukemia.<sup>69</sup>

## Diffuse Intravascular Coagulation

The syndrome of diffuse intravascular coagulation or DIC (disseminated intravascular coagulation, defibrination syndrome, consumption coagulopathy,<sup>250</sup> intravascular coagulation-fibrinolysis [ICF] syndrome<sup>234</sup>) has been one of the most intensively studied subjects in the field of hematology during the last decade, and investigation of the more general importance of DIC as an "intermediary mechanism of disease"<sup>208</sup> has led far afield. The development of new and highly

sensitive diagnostic techniques has resulted in the recognition of DIC in a seemingly endless variety of clinical situations.

### Etiology and Incidence

DIC has been well documented in association with the disorders summarized in Table 38-3. The true incidence of the syndrome is unknown. In many of the disorders listed, DIC develops only in an occasional case. Thus, it is rare in heat stroke,<sup>115,263</sup> in "auto-immune" disorders,<sup>140</sup> and in hemolytic anemias.<sup>109</sup> The incidence of DIC in association with many disorders appears to be proportional to the energy with which the diagnosis is pursued, eg, septicemia, intrauterine fetal death.

Available evidence does not justify the conclusion that DIC is a major pathophysiologic feature in thrombotic thrombocytopenic purpura<sup>170,196</sup> (page 943), eclampsia,<sup>239</sup> the hemolytic uremic syndrome,<sup>170,283a</sup> various forms of chronic renal disease,<sup>236</sup> and severe liver disease.<sup>115</sup> That many hold the opposite view should be noted, however, and the pathophysiologic importance of DIC in these disorders remains unsettled. Further details are given elsewhere.<sup>115,143,153,167,208,212,236,250</sup>

### Pathophysiology

The pathophysiology of DIC is complicated and poorly understood.<sup>218</sup> Acute DIC usually is a medical emergency; complete studies are difficult to obtain, and, even in cases that can be carefully evaluated, the physician is confronted with the end result of a complex sequence of interrelated events that can seldom be reconstructed. As a result, present concepts in the main are based on *in vitro* experiments and studies in lower animals. The relevance of such data to human disease has yet to be clearly established.

The mechanisms by which DIC is initiated are numerous,<sup>223</sup> but all have in common the capacity, in terms of either the magnitude or the duration of the activating stimulus, to exceed or "overwhelm" normal compensa-

\*May produce a similar syndrome in the fetus as a result of maternal to fetal blood passage.<sup>17</sup> 191

tory processes (Fig. 38-2). Thrombin is persistently or recurrently elaborated within the circulation, and the process of DIC, like normal coagulation, becomes "autocatalytic." Fibrinogen, various other coagulation factors, and platelets are utilized, and fibrin formation begins. The fibrinolytic enzyme system is activated, and large amounts of fibrin degradation products (FDP) are produced. These further impair hemostatic function. Bleeding, shock, and vascular occlusion commonly supervene, and produce profound alterations in the function of virtually every organ system. Normal compensatory processes may become impaired so as to create a self-perpetuating "vicious cycle." The ultimate outcome is determined by a dynamic interplay between the various pathologic processes and compensatory mechanisms, ie, fibrin deposition vs fibrinolysis; depletion vs reple-

tion of coagulation factors and platelets; production vs clearance of fibrin, FDP, and other products of coagulation.

### **Mechanisms by Which DIC is Initiated**

The mechanisms that activate or "trigger" DIC act upon pathways that are involved in normal hemostasis, namely, the processes of platelet adhesion and aggregation, and the contact and tissue-activated pathways of coagulation. In most forms of DIC the initiating factors are multiple and interrelated. For example, in meningococcemia, endothelial injury may lead to the release of thromboplastins and collagen exposure which initiates platelet adhesion, aggregation, and contact activation; and endotoxemia also produces platelet aggregation and contact activation.

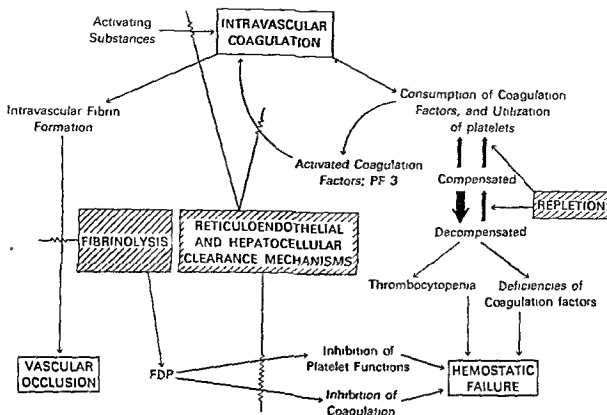

Fig 38-2. The pathophysiology of diffuse intravascular coagulation. The major compensatory processes are illustrated in hatched blocks.

**THROMBOPLASTIC SUBSTANCES.** The entry of thromboplastic substances into the general circulation from endogenous sites ("autoinfusion") presumably is a contributory factor in most forms of DIC, and is of major pathogenetic importance in cases associated with abruptio placentae, intrauterine fetal death, amniotic fluid embolism,<sup>256</sup> and various neoplasms. In abruptio placentae,<sup>273</sup> decidual fragments, serum containing activated coagulation factors, and other material from the placental site enter the intervillous "maternal lake" and hence the venous circulation. This process is initiated by rupture of the basal decidual plate, and has been termed "auto-extraction."<sup>256</sup> The deposition of fibrin in the retroplacental clot is of minor importance, even though such clots may be massive.<sup>239</sup>

In amniotic fluid embolism, relatively weak thromboplastins together with large amounts of particulate matter enter the circulation suddenly. If the patient survives this circu-

latory catastrophe, DIC develops. In intra-uterine fetal death, thromboplastic substances from the dead fetus are slowly but continuously absorbed, producing a picture of chronic but progressive DIC<sup>239</sup>; rarely, acute DIC with marked fibrinogenolysis may be associated.<sup>240</sup> In neoplasms, breakdown products from the tumor and tumor micro-emboli are thought to enter the circulation and act as thromboplastins. Some neoplasms secrete thrombin-like enzymes,<sup>190a</sup> or fatty acids which alone, or when combined with albumin,<sup>154</sup> act as thromboplastins.<sup>233</sup>

In DIC associated with massive trauma,<sup>209</sup> major surgical procedures, or large burns, thromboplastic substances from damaged tissues are presumably the major initiating factor. In such cases, antecedent abnormalities ("hypercoagulability," azotemia) and complications (shock, intravascular hemolysis, massive transfusions of stored blood (page 1102), septicemia, hypoxia) are important con-

tributory factors.<sup>114,136</sup> Various circulatory-assist devices that are employed during surgical procedures may produce hemolysis, activation of factor XII, platelet damage, and denaturation or utilization of fibrinogen and other coagulation factors.<sup>278</sup>

**INFECTIONS.** The frequency with which DIC accompanies meningococcemia and septicemia due to other bacteria that possess potent endotoxins has led to intensive study of the effects of endotoxin on the hemostatic apparatus. Purified *endotoxin* produces several effects that may lead to DIC, namely, activation of factor XII,<sup>204</sup> platelet aggregation,<sup>245</sup> inhibition of fibrinolysis, leukocyte aggregation, direct endothelial injury,<sup>207</sup> and impairment of compensatory clearance functions.<sup>123</sup> The coagulation abnormalities and the histopathologic appearance of the lesions produced by endotoxin in the generalized Sanarelli-Shwartzman phenomenon in animals resemble those found in human DIC.<sup>287</sup> Studies of this animal model have been intensive,<sup>123,205,223,232,249,251</sup> and have revealed the following of particular pertinence to DIC in man: (1) Shwartzman-like phenomena may be produced by agents other than endotoxin, such as factor Xa,<sup>251</sup> substances that produce contact activation and platelet aggregation,<sup>214</sup> and purified platelet factor  $3^{249}$ ; (2) the infusion of FDP, tissue thromboplastin, red cell hemolysates, and inhibitors of fibrinolysis produces changes that simulate the effects of reticuloendothelial blockade; (3) heparin, coumarin anticoagulants, granulocytopenia,<sup>197</sup> thrombocytopenia,<sup>202</sup> activators of endogenous fibrinolysis, and inhibitors of factor XII activation inhibit the Shwartzman phenomenon; (4) continuous slow infusion of endotoxin produces DIC in the absence of either a "priming dose" or reticuloendothelial blockade<sup>5</sup>; and (5) the Shwartzman phenomenon can be produced in pregnant animals with only one dose of endotoxin. The pertinence of these data to human disease nevertheless remains uncertain.<sup>115</sup> The Shwartzman phenomenon and the effects of endotoxin in general are highly species specific, the pathophysiologic role of endotoxi-

nemia in human sepsis is by no means clear,<sup>206</sup> and DIC may complicate acute infections due to bacteria lacking potent endotoxins, eg, pneumococci.<sup>126,286</sup> In meningococcemia and other forms of endotoxemia,<sup>207</sup> direct vascular injury results in the release of thromboplastins, and even endothelial cells,<sup>129</sup> into the general circulation, and may be the major factor in the initiation of DIC. A similar phenomenon may be involved in rickettsial and viral infections. In malaria,<sup>142</sup> massive intravascular hemolysis may occur. In most severe infections, the complicating influence of "septic" shock may be considerable, as will be discussed below.

**SHOCK AND HYPOPERFUSION.** The relationship between various forms of shock and DIC has not been clearly defined. It has been suggested that DIC is involved in all forms of shock, and that it is the central feature in irreversible or refractory forms.<sup>167,168</sup> However, the evidence that uncomplicated hemorrhagic shock initiates DIC is unconvincing.<sup>114,234</sup> In septic shock, the interrelationships between septicemia, shock, and endotoxemia are exceedingly complex, and studies in lower animals must be interpreted with caution because of marked and unexplained differences in the responses of various species.<sup>138</sup> In septicemia, both thrombocytopenia and "septic shock" may occur without DIC. An overriding problem in interpreting all of these data is the difficulty in distinguishing between causes and effects.

Although the importance of shock as a "trigger" factor in DIC is unclear, shock may nevertheless play an important pathophysiologic role. Hypoperfusion, even of normal vessels, acidosis,<sup>135</sup> and hypoxemia produce "hypercoagulability" and favor platelet aggregation.<sup>115</sup> Furthermore, splanchnic hypoperfusion produces a marked impairment of reticuloendothelial and hepatic clearance functions, and is present in virtually all forms of shock. Thus, shock may favor the development of DIC from activating stimuli that ordinarily would not exceed the capacity of compensatory processes, and may perpetuate

DIC, after a transient activating stimulus has been dissipated. Shock also may impair hepatic synthesis of coagulation factors, and thus contribute to the coagulation defect in DIC.

DIC in association with giant hemangiomas (Kasabach-Merritt syndrome),<sup>165,175</sup> or with aneurysms of the aorta<sup>181</sup> or other large vessels,<sup>125</sup> has been attributed to *hypoperfusion of local vascular beds*. The pathophysiologic role of hypoxemia in DIC associated with cyanotic congenital heart disease is obscure.<sup>124</sup>

**MISCELLANEOUS ACTIVATING STIMULI.** There is good experimental evidence that various processes in addition to those described above may initiate DIC, and multiple "trigger" factors usually complicate the clinical situation. Thus, factor XII is activated by saturated fatty acids in vitro, but the importance of such lipids in the pathogenesis of fat embolism remains unclear.<sup>131</sup> Antigen-antibody complexes produce platelet aggregation and also activate factor XII in vitro, and it has been suggested that such complexes, or cytotoxic antigen-antibody reactions, play an important role in DIC associated with acute anaphylactic reactions,<sup>219</sup> purpura fulminans (page 1219),<sup>174</sup> and transfusion of incompatible blood.<sup>247</sup> When incompatible blood has been given, the release of ADP from hemolysed red cells also may be involved.<sup>236</sup> The infusion of trypsin and other proteolytic enzymes may induce DIC in animals, and the venoms of various snakes contain similar enzymes. Crude venoms also contain substances that act as thromboplastins, and produce intravascular red cell hemolysis and massive vascular damage.<sup>250</sup>

The pathophysiology of DIC in association with acute leukemia is unclear. This syndrome has been described in all of the morphologic forms,<sup>118,137,147,193</sup> but is most common in the promyelocytic variety.<sup>272</sup> The granules of various "blast" forms contain thromboplastic substances,<sup>160,161</sup> the promyelocyte containing particularly high concentrations.<sup>161</sup> Lysosomal fractions of myeloblasts and promyelocytes exhibit fibrinolytic ac-

tivity in vitro, whereas those of lymphoblasts are procoagulant.<sup>137</sup> In one patient, lysozymes were isolated from the urine, and it was suggested that these originated in leukemic cells and were the cause of DIC.<sup>193</sup>

### *Consumption of Coagulation Factors*

DIC constitutes a model of accelerated turnover of various coagulation factors, whose levels at any time are determined by the size of the plasma pool and the differences between the rates at which they are being destroyed and replenished. Quantitative studies have demonstrated accelerated turnover rates for platelets, fibrinogen, and prothrombin.<sup>170,185,234</sup> There are no quantitative data concerning other coagulation factors. Numerous factors complicate a simple kinetic approach. For example, circulating FDP may induce the release of large amounts of fibrinogen into hepatic lymph,<sup>121</sup> and also increase the rate of fibrinogen synthesis as much as four-fold.<sup>185</sup> Other complexities include impaired hepatic synthesis of coagulation factors, and the phenomenon of post-depletion "rebound."

Generalizations based on the consumption of coagulation factors during in vitro coagulation (page 430) (Table 10-2, page 411) are not always consistent with laboratory findings in DIC.<sup>229</sup> Thus, factors that normally are not consumed may be deficient in DIC; eg, factors VII, IX, X. Prothrombin, which is completely consumed in vitro, often is normal in DIC. Significant hypoprothrombinemia must reflect either massive and protracted activation of coagulation or complicating factors, since, in animals, severe depletion of platelets, fibrinogen, and factors V and VIII results from activation of only 10% of plasma prothrombin.<sup>243</sup>

Substances other than coagulation factors may be depleted as a result of DIC. Those of homeostatic importance include antithrombin III<sup>282</sup> and plasminogen. The latter has great avidity for fibrin, and may coprecipitate in fibrin thrombi.<sup>246</sup>

### Utilization of Platelets

In DIC, the platelet count often is depressed out of proportion to coagulation abnormalities. This presumably reflects the limited production capacity of the megakaryocyte. Thrombocytopenia may result from processes other than the utilization of platelets in thrombotic lesions.<sup>236</sup> These processes include adhesion to denuded or damaged endothelial surfaces and intravascular aggregation with subsequent sequestration, which may be caused by endotoxin,<sup>123</sup> antigen-antibody complexes, thrombin, particulate matter,<sup>283</sup> and possibly fibrin-FDP complexes.<sup>120</sup>

All of the factors described above initiate the platelet release reaction<sup>155</sup> (page 394). The resulting platelet factor 3 activity may further accelerate the process of DIC,<sup>249</sup> and may contribute to impairment of clearance functions. Epinephrine and 5-hydroxytryptamine (serotonin) are released from the platelets and may reach extremely high concentrations in hypoperfused vascular beds. This process may produce sustained constriction of the afferent renal arteriole and may predispose to cortical necrosis. 5-Hydroxytryptamine also may produce pulmonary<sup>271</sup> and cerebral hypoperfusion.<sup>114</sup> The hypotensive effects of bradykinin and kallikrein,<sup>205</sup> which are activated by factor XIIa and by plasmin, and obstruction of the pulmonary vasculature produced by fibrin,<sup>230</sup> also may be significant.<sup>205</sup>

### Fibrin Formation

The formation of fibrin, in the form of small strands and "microclots,"<sup>253</sup> is the immediate result of DIC; the ultimate consequence of this process is determined by a balance between the rate of fibrin formation and the rate at which it is cleared from the circulation or lysed by the fibrinolytic enzyme system. Vascular occlusion, if it develops, presumably is the result of "embolic" thrombosis.<sup>211</sup> The localization of fibrin thrombi in animals with experimentally induced DIC can be varied in a remarkably

specific manner by pretreatment with various agents.<sup>210</sup> For example, sympathomimetic amines and angiotensin<sup>283a</sup> promote renal cortical involvement; corticosteroids favor fibrin deposition in the adrenal gland. Ischemic necrosis of certain tissues, particularly the renal cortex,<sup>218</sup> may result from transitory or low-grade DIC. It has been suggested that, in purpura fulminans, the initiating infection, or antigen-antibody complexes formed as a result thereof, serves to "condition" the skin in such a manner that it becomes susceptible to ischemic necrosis during subsequent intravascular coagulation.<sup>174</sup> This phenomenon has been compared to the local Schwartzman phenomenon and the Arthus phenomenon.<sup>175</sup>

Erythrocytes are mechanically injured during passage through fibrin networks in the microcirculation. Such *microangiopathic hemolysis* leads to the production of schistocytes and microspherocytes (Chapter 28).

### Fibrinolysis

Fibrinolysis is present in virtually every patient with DIC,<sup>219</sup> but plays a homeostatic rather than a pathologic role. It may be activated by several mechanisms. The major endogenous source of plasminogen activators is in the vascular endothelium of the microcirculation and, in DIC, such activators are apparently released as a result of endothelial injury or hypoxia. Most of the thromboplastic substances that initiate DIC also contain plasminogen activators,<sup>235</sup> eg, amniotic fluid, tumor tissues, extracts of leukemic cells.<sup>137</sup> There is good experimental evidence that the release of plasminogen activators from platelets and leukocytes also may be significant.<sup>138</sup> Finally, factor XIIa and thrombin activate plasminogen directly.<sup>232</sup>

*Fibrinolysis* must be clearly distinguished from the process of *fibrinogenolysis* in which fibrinogen and other coagulation factors are proteolytically destroyed in the circulation. Fibrinogenolysis is uncommon in DIC,<sup>115,179,219</sup> and when present is usually transitory and is overshadowed by marked

fibrinolysis. Disorders in which fibrinogenolysis presumably arises in the absence of DIC are discussed below.

### *Fibrin Degradation Products*

The step-wise process by which fibrin is proteolytically degraded and the biologic effects of the various products of the process (FDP) were discussed in Chapter 10 (Fig. 10-8, page 437).<sup>201</sup> These protein fragments inhibit several steps in coagulation,<sup>151,152,261</sup> produce a structurally defective fibrin polymer,<sup>107,119</sup> impair platelet functions<sup>269</sup> (page 438), and may constrict the pulmonary vasculature.<sup>122a,156</sup> It has now become apparent that the presence of large amounts of FDP in the circulation is a major factor in the production of hemorrhage in patients with DIC.

A large amount of fibrin remains in a soluble state as a consequence of the formation of complexes between fibrin monomers, various FDP, and fibrinogen (page 438). This has been regarded as a final defense against vascular occlusion.<sup>225</sup> In vitro, the complexes dissociate in the presence of alcohol<sup>133</sup> or protamine sulfate<sup>237</sup> to form gels or precipitates of various types (*paracoagulation*). There is indirect evidence that basic proteins from the granules of neutrophils<sup>172</sup> and factor 4 released from platelets<sup>199</sup> (page 398) may act as paracoagulants in vivo; ie, they may convert soluble fibrin-FDP complexes into particulate fibrin.

### *Impairment of Clearance Mechanisms*

The numerous processes that normally remove procoagulant material from the circulation (page 432) are of the utmost importance in DIC because of the presence of massive amounts of both activators and products of coagulation. There is good evidence that most of the products of intravascular coagulation (free fibrin,<sup>236</sup> prothrombinase,<sup>268</sup> platelet factor 3 activity, various types of FDP and complexes thereof<sup>156</sup>), as well as various initiators of the process (tissue

fragments, endotoxin, antigen-antibody complexes, thromboplastins, red cell stroma<sup>268</sup>) are removed from the circulation by the reticuloendothelial system,<sup>184,248</sup> the Kupfer cells of the liver being of particular importance (Fig. 38-2). In certain forms of DIC, large amounts of relatively inert particulate matter place an additional burden on the reticuloendothelial system, eg, amniotic fluid embolism. The hepatic cells are of primary importance in the clearance of activated coagulation factors (IXa,<sup>144</sup> Xa, and XIa<sup>115</sup>). It has been suggested that, in DIC, various substances saturate and produce an "autoblockade" of reticuloendothelial and hepatic clearance functions in a manner comparable to that produced experimentally in the Schwartzman reaction.<sup>194,223</sup> This may be an important pathophysiologic factor, particularly in perpetuating DIC following a transient activating stimulus. Other factors may indirectly contribute to "autoblockade" of clearance functions, including shock and endotoxemia, both of which produce marked hepatic hypoperfusion.<sup>123,138</sup>

### *Chronic or "Compensated" DIC*

Certain forms of DIC result from a weak or intermittent activating stimulus. In such patients, a balance is reached between destruction and production of coagulation factors and platelets (Fig. 38-2). The pathophysiology of such chronic, subacute, or "compensated"<sup>234</sup> DIC is fundamentally the same as that in the acute case. The distinction is nevertheless valuable, since the clinical picture and laboratory findings in the chronic form are more variable than in the acute one and may be diagnostically confusing.

Chronic DIC has been described in most cases of intrauterine fetal death and giant hemangioma (Kasabach-Merritt syndrome),<sup>169</sup> and in many cases of disseminated cancer. Other etiologic factors include various forms of vasculitis,<sup>181</sup> acute leukemia,<sup>194</sup> aneurysms,<sup>181</sup> hemangiomatous transformation of the spleen,<sup>260</sup> degenerating leiomyomas and hydatidiform moles, amyloidosis,<sup>130</sup> and metastatic carcinoid.<sup>145</sup>

Chronic DIC has many clinical and laboratory features that resemble an intermediate stage between the "hypercoagulable state" (page 1237) and acute DIC, an observation of more than theoretic interest. In cancer, a virtually continuous spectrum of clinical and laboratory features has been described; these range from recurrent thrombosis with high levels of platelets and coagulation factors to acute DIC with severe hemorrhage. There is incontrovertible clinical and experimental evidence that pregnancy, the best studied form of "hypercoagulability," is associated with a marked propensity for the development of DIC.<sup>223,286</sup> Indeed, it has been suggested that even normal pregnancy is a form of "low-grade" DIC,<sup>184</sup> and tissue thromboplastin can be recovered from the serum of normal postpartum women.<sup>277</sup> It is thus possible that the hypercoagulable state represents merely very slow intravascular coagulation, as discussed on page 1237.

#### *DIC in Neonates and Infants*

Several disorders unique to the neonate and infant may be associated with DIC.<sup>191,284</sup> The transplacental passage of thromboplastin or other activating substances was the apparent cause of DIC in neonates born of mothers affected with DIC due to abruptio placentae,<sup>149</sup> toxemia,<sup>195</sup> or septicemia. The development of DIC in a neonate following the intrauterine death of a twin fetus was attributed to "fetofetal" passage of thromboplastins.<sup>221</sup> Generalized virus infections (herpes simplex, cytomegalic inclusion disease, rubella) are common causes of DIC in infants.<sup>171</sup> DIC secondary to giant hemangiomas and purpura fulminans has been reported in neonates. Well-documented cases of DIC have been reported in infants with the acute respiratory distress syndrome.<sup>171,203,264</sup> The incidence of DIC in association with this syndrome and the importance of neonatal hypoxia in general have yet to be established. Some findings suggesting DIC have been noted in infants with hemolytic disease of the newborn (Chapter 54), but detailed studies are lacking. Even less clear is the hypothe-

sized role of DIC in hyaline membrane disease.<sup>271</sup>

#### *Clinical Picture*

The major clinical features of DIC are bleeding, often of serious magnitude and abrupt onset, a variable element of shock that is often out of proportion to apparent blood loss, and symptoms of hypoperfusion of various vascular beds. Acute renal failure is commonly present, and thromboembolic manifestations are not uncommon.<sup>143,219</sup> Any of these features, or signs and symptoms of the underlying disorder, may predominate in a given case.

#### *Acute DIC*

Bleeding manifestations of virtually every kind have been described, and evolve rapidly in the patient with acute DIC. The first evidence often pertains to the underlying disorder. In abruptio placentae, shock develops rapidly; vaginal bleeding may be minimal or absent for a time and bears little relationship to the extent of abruption.<sup>239</sup> In cases that develop following surgical procedures, alarming hemorrhage may develop around drains and tracheostomies, and large accumulations of blood may be concealed in serous cavities. Generalized ecchymoses, petechiae, and bleeding from previously intact venipuncture sites or around indwelling intravenous needles or catheters are present in many patients. Large, spreading, hemorrhagic skin lesions often are superimposed on familiar exanthems in patients with rickettsial and viral infections. In patients with meningococcemia, cutaneous hemorrhage may be striking. Bleeding from apparently normal gingivae, epistaxis, gastrointestinal bleeding, and hematuria are very common.

In some forms of DIC, bleeding may not be immediately apparent, e.g., in septicemia due to gram-negative bacilli. In septic abortion, shock and acute renal failure often dominate the picture, as does evidence of acute cor pulmonale in amniotic fluid embolism and fat embolism.

**PURPURA FULMINANS.** In this disorder, hemorrhagic manifestations develop several days after an acute infection, usually of streptococcal origin. The most common manifestations are symmetrical ecchymoses of the lower extremities and buttocks, sharply circumscribed infarcts of the skin ("purpura necrotica") and genitalia, and gangrene of the extremities ("purpura gangrenosa") that often involves the digits symmetrically.<sup>148</sup> Petchiae are reportedly rare. Fever and prostration usually are marked, but visceral lesions, including renal involvement, are relatively uncommon.

### **Chronic DIC**

Superficial but extensive ecchymoses of the extremities, often without petechiae, may develop intermittently or may persist for weeks or months. Recurrent episodes of epistaxis or more serious internal mucosal bleeding may punctuate the course. Thromboembolic phenomena are very common, and frequently are the presenting complaints. Thrombophlebitis may develop in unusual sites, eg, the axillary vein. The picture of thrombophlebitis that repeatedly recurs after anticoagulant therapy has been stopped is not uncommon. More serious hemorrhagic manifestations may develop as the underlying disease progresses, or may arise with dramatic suddenness following surgical procedures, eg, prostatectomy. Acute DIC may be heralded by further thrombophlebitis or pulmonary emboli. In some patients, signs suggesting vascular obstruction may develop with little bleeding, eg, impairment of renal function, confusion, transitory neurologic syndromes, or repeated episodes of cerebral thrombosis. In intrauterine fetal death, bleeding is seldom serious, but progressive impairment of renal function is common.

### **Laboratory Diagnosis**

The laboratory findings in DIC are summarized in Table 38-2. Contrary to what is commonly assumed, they are quite variable. The plasma fibrinogen level, thrombin time,

platelet count and estimates of FDP, and, to a lesser extent, the PTT and prothrombin time are the cornerstones upon which the diagnosis of DIC is based. These simple tests should always be obtained first. Additional information may confirm but seldom refutes the diagnosis of DIC if typical abnormalities are demonstrated by these tests. A possible exception to this generalization is DIC in neonates or infants, in whom results of one-stage screening tests are more variable than in adults (page 1067).<sup>171</sup> Laboratory data change with remarkable rapidity in DIC, and in doubtful cases it is often important to repeat the simple tests at frequent intervals, even every four to eight hours.

Laboratory data must be interpreted with unusual caution in DIC. Levels of platelets and various coagulation factors, fibrinogen and factor VIII in particular, may be markedly elevated in most of the conditions associated with DIC, including pregnancy. Thus, a fibrinogen level of 200 mg/dl, although within the normal range determined in healthy subjects, may represent a marked drop in a patient whose baseline level was 800 mg/dl.

### **Basic Blood Examinations**

In DIC, routine hematologic tests may reveal evidence of acute bleeding, accelerated red cell destruction, or signs of the underlying disease. Examination of the blood smear may reveal schistocytes, and more subtle evidence of intravascular hemolysis is commonly found, eg, increased serum levels of lactic acid dehydrogenase, decreased haptoglobin. Rarely, massive intravascular hemolysis with hemoglobinemia and hemoglobinuria may be present.<sup>253</sup>

Thrombocytopenia is an early and consistent sign of DIC; it is difficult to entertain this diagnosis in the presence of a persistently normal platelet count. Platelet counts in the range of 50 to 100 × 10<sup>9</sup>/l are the usual finding, but severe thrombocytopenia may be present. In patients with DIC due to gram-negative septicemia, thrombocytopenia may develop before coagulation abnormalities ap-

pear,<sup>123</sup> whereas in those with DIC due to infection with gram-positive bacteria, and in those having other forms of DIC, the platelet count often falls simultaneously with the fibrinogen level. The bleeding time is usually prolonged even when the platelet count is only moderately depressed, presumably as the result of the impairment of platelet function by FDP.

### *The Coagulation Defect*

The PTT, prothrombin time, and thrombin time are prolonged in most patients with acute DIC. The thrombin time usually is not normalized by the admixture of the patient's plasma with an equal volume of normal plasma. In an occasional patient, "late" or small FDP predominate and the thrombin time may be normal. Early in the course of acute DIC, and in chronic DIC, the PTT may be normal, or even shorter than normal as the result of the procoagulant effects of activated coagulation factors. The coagulation time of whole blood varies widely; it may be shortened, normal, or prolonged. Truly incoagulable blood is not common, but the clot that forms in the presence of hypofibrinogenemia may be small, friable, and "wispy," and may be trapped within sedimented erythrocytes. This artifact (the "fall-out" phenomenon) often is attributed to fibrinolysis. Much has been written about the importance of "observing the clot,"<sup>239</sup> but this procedure seldom provides definitive information and may seriously mislead the inexperienced observer.

There are few patients in whom the process of DIC can be followed from its inception and specific assays for various coagulation factors obtained at the time of diagnosis reveal a variable and rapidly changing picture. The plasma levels of fibrinogen and of factors V, VIII, and XIII usually are significantly depressed; fibrinogen and factor V are the most consistently affected.<sup>219</sup> The level of factor X may be lower than that of other "stable" factors (factors VII, IX, and XI), which usually are present in normal amounts.<sup>219</sup> In many patients, particularly

those with abruptio placentae, normal prothrombin levels are maintained,<sup>219,273</sup> but marked hypoprothrombinemia often is present in those with septic DIC.<sup>141</sup> In patients with chronic DIC, prothrombin deficiency is unusual, whereas significant deficiencies of factor X often are present.<sup>219</sup> Marked deficiencies of all factors have been described in some patients.

The levels of factors VIII, IX, and XI as determined by one-stage assays may fluctuate widely as the result of the presence of activated factors,<sup>224a</sup> eg, thrombin,<sup>236</sup> factor Xa.<sup>141</sup> This problem is minimized in two-stage assays employing the thromboplastin generation test (page 1057).<sup>219,229</sup> In many patients, the levels of coagulation factors tend to "overshoot" after repletion, and in some a cycle of depletion and "overshoot" gives rise to very confusing data.<sup>115,212,236</sup> Fibrinogen levels may be overestimated by turbidimetric and certain precipitation methods, and, as the consequence of the inhibitory effects of FDP, the fibrinogen titer and the serial thrombin time may be prolonged out of proportion to the fibrinogen level.

### *Tests for Fibrinolysis and FDP*

Both the whole blood clot lysis time and the euglobulin clot lysis time are normal in most patients with DIC. In the presence of severe hypofibrinogenemia, the euglobulin clot may be too small to allow accurate measurement of lysis time. Moreover, even when plasminogen activators are present in high concentrations, the euglobulin lysis time may be normal or prolonged due to plasminogen depletion. Techniques in which an exogenous source of fibrinogen and plasminogen is provided circumvent these difficulties.<sup>11,113</sup>

If FDP levels are estimated by means of the Fi reagent, titers of 1:8 or less can be regarded as normal,<sup>28</sup> and, in most patients with DIC, titers of 1:50 or higher will be found. With quantitative methods, such as staphylococcal clumping<sup>173</sup> or red cell bemaagglutination inhibition,<sup>28</sup> normal levels of FDP, expressed as "fibrinogen equivalents," range up to 8  $\mu\text{g}/\text{ml}$ . In most patients with

DIC, levels of 25  $\mu\text{g/ml}$  or higher will be found.<sup>219</sup> All methods are more sensitive to large or "early" FDP. These fragments, particularly fragment  $X_2$ ,<sup>236</sup> may retain thrombin-binding sites or may form a complex with fibrinogen, and consequently may be removed during the preparation of serum for FDP tests. This is one explanation for the absence of FDP in an occasional patient with otherwise typical DIC. Tests for FDP and the euglobulin lysis time are unreliable when performed on cord blood.

"Paracoagulation" techniques are simple to perform but are much less specific than tests for FDP.<sup>286a</sup> The ethanol gelation test<sup>133</sup> is much less sensitive than tests for FDP and frequently is negative in DIC.<sup>164</sup> To the contrary, results of protamine gelation tests<sup>227,257</sup> usually are positive, but abnormal results are obtained in numerous other disorders, including many that frequently are associated with DIC.<sup>164</sup> Such tests are valuable as "broad-spectrum" screening procedures. "Cryofibrinogen" may be present,<sup>198,253,263</sup> and should not be confused with small insoluble clots that are frequently found in plasma samples.

### Miscellaneous

The survival time of <sup>125</sup>I-labeled fibrinogen<sup>117</sup> and the rate of incorporation of <sup>14</sup>C-labeled glycine ethyl ester into soluble "circulating fibrin"<sup>182</sup> are exceptionally sensitive indicators of DIC, and may be significantly abnormal even in patients with normal levels of FDP. The third component of complement is decreased in many patients with DIC.<sup>163,279</sup>

### Differential Diagnosis

There are relatively few causes of serious hemorrhage of abrupt onset in a patient who was previously free of bleeding, and there are very few acquired disorders that give rise to significant coagulation abnormalities in which the cause is not obvious. Thus, the syndrome of DIC is seldom difficult to recognize. Most

often, problems arise when the diagnosis simply is not considered, or, in the chronic forms, when the underlying process may be masked by features of the basic disease or by thromboembolic complications. In patients with carcinoma and chronic DIC, laboratory evidence of microangiopathic hemolytic anemia may be the major finding.<sup>117,180,259</sup> In promyelocytic leukemia, intravascular coagulation may proceed at a very slow rate,<sup>162</sup> but thrombosis is a common complication.<sup>310</sup>

Two disorders, however, produce laboratory abnormalities that resemble DIC, ie, severe liver disease, which is very common, and fibrinogenolysis or "pathologic" fibrinolysis, which is very rare (Table 38-2).

In *fibrinogenolysis* (page 1224), the presence of hypofibrinogenemia, FDP, abnormalities in the PTT, prothrombin time and thrombin time, and deficiencies of factors V and VIII may be noted, but the platelet count usually is normal, and the euglobulin lysis time is markedly and persistently shortened, often in association with plasminemia. Schistocytes are not seen in association with fibrinogenolysis, unless they are the result of an underlying disorder. Hypoprothrombinemia and deficiencies of stable coagulation factors VII, IX, X, and XI are very rare in fibrinogenolysis, and the results of paracoagulation tests are normal.<sup>117</sup>

In *liver disease*, coagulation abnormalities and thrombocytopenia may originate from many pathologic processes (page 1205). Chronic or intermittent fibrinogenolysis with high levels of FDP is commonly present, particularly in cirrhosis.<sup>11</sup> In such patients, the exclusion of DIC may be very difficult. In contrast to DIC, factor VIII levels are usually elevated in severe liver disease, and the levels of factors VII and IX usually are low.

DIC may be confused with various *microangiopathic hemolytic anemias* (Chapter 28), particularly with thrombotic thrombocytopenic purpura and the hemolytic uremic syndrome, disorders in which the clinical picture may resemble that of DIC in many respects. High levels of FDP may be encountered in the microangiopathic hemolytic anemias, but

coagulation abnormalities are not commonly present.<sup>196,236</sup> Many other disorders may produce significant elevations of FDP, eg, pulmonary embolism, chronic renal disease.

Moderate thrombocytopenia is a common consequence of the use of extracorporeal circulatory devices, and marked coagulation abnormalities often are noted immediately following their use because of the presence of residual amounts of heparin. Heparin levels may also rise several hours later (the "rebound" phenomenon).<sup>166,237</sup> In such patients, the presence of thrombocytopenia together with the effects of heparin may result in a state that will be confused with DIC. Similar difficulties in differentiation may arise following hemodialysis. Even the small amounts of heparin required to irrigate indwelling catheters are a common cause of "pseudo-DIC."

## Treatment

### Anticoagulants

The rationale for the use of heparin in the treatment of DIC would seem clear-cut. This drug is a potent and specific antagonist of thrombin and also inhibits various steps in coagulation (page 1239), and thus can rapidly neutralize free thrombin and retard or stop its further formation. The therapeutic efficacy of heparin is unquestionable in some animal models of DIC, but assessment of its effectiveness in man has proved more difficult. Heparin has been given concomitantly with numerous other agents to most patients with DIC. In those with acute forms of DIC in which the activating stimulus is transitory, eg, abruptio placentae, spontaneous cure is the rule. It should be remembered that heparin does not alter the basic disease process that is responsible for intravascular coagulation. In view of the complexity of DIC it is apparent that inhibition of coagulation alters only one facet, albeit a fundamental one, of the pathophysiologic cycle.

In chronic DIC the results of heparin therapy usually are favorable and may be dramatic.<sup>115,130,179,212</sup> In most subjects, heparin

would not be expected to alter ultimate mortality because of the nature of the underlying diseases, but, in the majority, this drug reduces the severity of bleeding and produces parallel improvement in laboratory abnormalities. The restoration of normal levels of the coagulation factors occurs roughly in inverse proportion to their biologic half-lives, but there are numerous exceptions to this rule. The laboratory picture of the "hypercoagulable state" frequently is seen following effective heparin therapy.<sup>115,229,242</sup> Fibrinolysis, if present, usually disappears following the administration of heparin, often before the coagulation defect has been alleviated.<sup>229</sup>

In acute DIC, particularly that associated with septicemia, results have been less encouraging.<sup>183</sup> In one series,<sup>141</sup> the alleviation of septic shock appeared to be more important in the ultimate prognosis than did correction of the coagulation abnormalities. Nevertheless, extant data do not justify the omission of heparin therapy in the treatment of DIC due to septicemia, even though such therapy has clearly been effective in only a minority of these patients. The administration of heparin together with adrenal corticosteroids has proved effective in a few patients with purpura fulminans.<sup>108,111,174</sup>

The apparent paradox of administering anticoagulants to a patient with a serious bleeding disorder has been emphasized repeatedly, but there is little evidence that heparin therapy is associated with unusual risk in DIC. Most workers have used standard dosage regimens (Table 39-1, page 1240), but some advise a reduction of the dosage in the face of marked thrombocytopenia.<sup>169</sup> Good therapeutic responses have been documented even with doses that do not significantly prolong the coagulation time.<sup>115</sup> Intermittent intravenous therapy (5,000 to 10,000 U/kg every four to six hours) or a continuous intravenous drip (1000 to 1500 U/hour) usually is preferred to administration by the intramuscular or subcutaneous route. Care should be used in patients with renal insufficiency and in those with severe hepatic disease, but neither condition contraindicates the use of heparin.

Laboratory control of heparin therapy is difficult in DIC. A rough estimate of the heparin level can be obtained from the coagulation time. Except in patients with severe hypofibrinogenemia, an adequate end point can usually be obtained. The results of the PTT are frequently erratic in the presence of DIC.

Heparin therapy is seldom required in patients with some forms of DIC. DIC that develops during or following extracorporeal circulation and other major surgical procedures often is transient. In abruptio placentae, DIC is rapidly reversible if the uterus is evacuated promptly; blood loss may be a major factor in the production of shock, and heparin may increase the risk of hemorrhage.<sup>239,250</sup> Heparin is seldom required in the management of chronic DIC associated with intrauterine fetal death, unless the dead fetus is carried for more than a month; then heparin should be administered only to patients who have a falling fibrinogen level and significant bleeding.<sup>239</sup>

There is no evidence that coumarin anticoagulants, except in unusually high and toxic doses,<sup>115</sup> are effective in the management of DIC, even in its chronic forms, and there are several reports detailing the recurrence of previously controlled DIC when heparin was replaced by coumarins.<sup>115</sup> The effects of dextran<sup>130</sup> and of inhibitors of platelet function such as aspirin have not been adequately evaluated.

#### *Replacement of Platelets and Coagulation Factors*

The value of replacement therapy in DIC is limited, first, because the deficiency of most coagulation factors is seldom marked, and, secondly, because the most significant factor in the production of bleeding probably is the presence of large amounts of FDP.<sup>143</sup> The value of fibrinogen administration is debatable. In theory, the infusion of fibrinogen in the presence of active DIC "adds fuel to the fire." Thromboembolic complications have developed in some patients following fibrinogen administration,<sup>212,236</sup> but, in a much

larger number, fibrinogen produced no apparent adverse effects, and the risk of thromboembolism is greatly minimized if the patients are receiving heparin. It is probable that fibrinogen administration should be restricted to the occasional patient with marked hypofibrinogenemia and significant bleeding, in whom DIC is self-limited or has been controlled by heparin, eg, in intrauterine fetal death, prior to surgical intervention. Fibrinogen is frequently administered to women with abruptio placentae following evacuation of the uterus,<sup>239</sup> particularly if immediate surgical treatment is required. Even this indication has been disputed, however.<sup>273</sup> An additional argument against the use of purified fibrinogen is the risk of hepatitis, which may develop in as many as 20% of patients.

Because platelets are repleted slowly following a major episode of DIC, platelet transfusions may be helpful in patients with severe thrombocytopenia. The administration of concentrates of specific coagulation factors is rarely indicated.<sup>176</sup>

#### *Miscellaneous*

Treatment of shock should be prompt and energetic in all patients with DIC. There is no evidence that transfusions of whole blood or plasma promote thromboembolic complications, and these components should be given promptly if indicated. There is experimental<sup>223</sup> and some clinical evidence<sup>127</sup> that corticosteroids accelerate DIC. Nevertheless, these hormones are commonly given to patients with purpura fulminans and to those with meningococcemia.

In theory, epsilon aminocaproic acid (EACA) and other antifibrinolytic agents (page 1226) remove the major antagonist of intravascular fibrin formation, and in several well-documented cases of DIC, their use has resulted in serious and even fatal thromboembolic complications.<sup>212,234</sup> The indiscriminate use of such drugs should be discouraged. EACA has been administered together with heparin<sup>187</sup> or after heparin in a few patients in whom DIC was associated with fibrinogenolysis. No serious adverse effects were

observed, but the therapeutic value of EACA was difficult to assess. Because of the potential risks, fibrinolytic enzyme inhibitors should be administered only to carefully selected patients; ie, those in whom DIC has resulted from a transitory stimulus or has been arrested by heparin administration, and in whom fibrinogenolysis, hypofibrinogenemia, and adequate renal function have been clearly documented.

It is possible that the therapeutic benefits of antifibrinolytic drugs outweigh potential adverse thromboembolic effects in many other forms of DIC, but this question cannot be answered with available data. The therapeutic use of EACA in fibrinogenolysis and appropriate dosage schedules are discussed on page 1226.

Agents such as *streptokinase* and *urokinase* activate the endogenous fibrinolytic enzyme system and have been used in some patients with DIC in an attempt to accelerate recanalization of thrombosed vessels after the acute process has been arrested. Preliminary results have ranged from equivocal to encouraging. It should be emphasized that the therapeutic margin between effective thrombolysis and fibrinogenolysis is perilously narrow.<sup>212</sup>

Exchange transfusion has been tried with some success in a few patients with DIC.<sup>264</sup>

## Pathology

The deposition of fibrin in small vessels represents the ultimate result of DIC. In many patients, fibrin can be formed and lysed without significant vascular occlusion. Indeed, in many autopsied subjects, fibrin thrombi were absent or were demonstrated only with special stains or by electron microscopy. This state may result from agonal lysis, or from deposition of thin films of fibrin on the vast endothelial surface and on the erythrocytes. The localization of fibrin thrombi varies somewhat with the cause of DIC. The usual distribution of lesions in the gut, pancreas, adrenals, brain, liver, skin, and kidneys has been well documented.<sup>208</sup> Renal lesions range from patchy tubular necrosis to

massive bilateral cortical necrosis.<sup>248</sup> Non-thrombotic endocarditis and pulmonary hyaline membranes have been found in some patients.<sup>177</sup>

## Fibrinogenolysis

The term "*pathologic fibrinolysis*" has been used indiscriminately for many years to refer to virtually any situation in which in vitro evidence of fibrinolysis was associated with bleeding. It seems probable, in retrospect, that in many cases fibrinolysis was secondary to DIC, and that in others it represented an essentially physiologic response to anoxia, shock, or stress.<sup>9</sup> It is improbable that fibrinolysis per se ever produces bleeding, although the lysis of hemostatically functional fibrin plugs may aggravate bleeding from other causes,<sup>211</sup> and may explain many cases of postoperative "oozing."<sup>185,288</sup> In *fibrinogenolysis* the proteolytic destruction of fibrinogen and other proteins occurs in the general circulation, and severe bleeding may develop. The pathophysiology of fibrinogenolysis remains unclear and in many instances it is probable that this process also represents a disproportionate or "inappropriate" response to underlying DIC, eg, in amniotic fluid embolism. Whether or not DIC is the common denominator in all cases of "pathologic fibrinolysis" and fibrinogenolysis is a question of great practical importance which cannot be answered with certainty.<sup>155a</sup> Since FDP presumably are major factors in the production of bleeding in fibrinogenolysis as well as in DIC,<sup>141,262</sup> antifibrinolytic agents would seem therapeutically desirable. However, these drugs are hazardous in the presence of DIC. This therapeutic "paradox" is presently insoluble.

## Etiology

It is questionable whether fibrinogenolysis ever develops in the absence of an underlying disease,<sup>9,219</sup> but this process may complicate various disorders, among which severe liver disease is by far the most common (page 1205). Fibrinogenolysis was the predomi-

nating laboratory feature in several patients with disseminated neoplasms,<sup>244,276</sup> and in others following extensive surgical operations,<sup>266</sup> particularly procedures involving the lung<sup>105,268</sup> and those performed for the correction of cyanotic congenital heart disease. Fibrinogenolysis has been reported in other disorders<sup>112</sup> including several that involve the hematopoietic system, eg, polycythemia vera,<sup>309</sup> acute and chronic leukemia,<sup>188</sup> and various lymphomas.<sup>62,132</sup>

### Pathophysiology

Fibrinogenolysis is a consequence of the activation of plasmin within the general circulation (*plasminemia*) (page 434). Potent plasma inhibitors (antiplasmins) normally neutralize free plasmin rapidly (Fig. 10-7, page 433), with the result that the proteolytic effects of this enzyme normally are restricted to fibrin, which is presumably its physiologic substrate. Fibrinogenolysis occurs only when the capacity of the antiplasmins is exceeded.

The proteolytic action of plasmin is quite nonspecific. In addition to fibrin and fibrinogen, this enzyme may degrade other coagulation factors<sup>267</sup> as well as a wide variety of other plasma proteins, eg, complement, various hormones.<sup>235</sup> Free plasmin may activate bradykinin, a phenomenon that may underlie the marked hypotension present in some patients with fibrinogenolysis.<sup>188</sup> "Pathologic proteolysis"<sup>262</sup> is thus an appropriate synonym for fibrinogenolysis.

Fibrinogenolysis is activated by mechanisms that are remarkably similar to those that initiate DIC. Thus, tumor tissues contain large amounts of plasminogen activators in addition to thromboplastins.<sup>105</sup> The sudden entry of such tissue extracts into the circulation may activate most of the circulating plasminogen instantaneously. Slower but more continuous "autoinfusion" presumably is involved in most cases, and it is probable that intravascular coagulation coexists in many. A similar process presumably explains the transient fibrinogenolysis that occurs following major surgical procedures.<sup>288</sup>

Hypoxia and hypoperfusion may lead to plasminogen activation, and, in an occasional patient, to fibrinogenolysis. However, in many of these patients, bleeding was minimal, and when present could not be clearly related to the presence of fibrinogenolysis. It is probable that, in these patients, fibrinogenolysis is a nonspecific essentially physiologic response. A similar conclusion has been reached regarding the majority of cases of "pathologic fibrinolysis" which develop following extracorporeal circulation.<sup>124,237,298</sup> Fibrinogenolysis may result from therapy with thrombolytic enzymes, as discussed on page 1247.

### Clinical and Laboratory Diagnosis

The clinical picture in most reported cases of fibrinogenolysis is quite similar to that present in DIC. The usual laboratory findings are summarized in Table 38-2 and are discussed on page 1221. Hypofibrinogenemia is seldom marked, and when found may in part represent an artifact due to in vitro lysis during processing of the blood sample. The PTT, prothrombin time, and thrombin time may be markedly prolonged, due mainly to the anticoagulant effects of FDP. Moderate concentrations of EACA ( $4 \times 10^{-4}M$ )<sup>288</sup> inhibit plasminogen activators but not free plasmin. Thus, the euglobulin lysis time, which in fibrinogenolysis invariably is shortened, is unaffected by the addition of EACA if free plasmin is present. Fibrinolysis in heated fibrin plates<sup>113</sup> also measures free plasmin, since plasminogen activators are thermolabile. Among the coagulation factors, factors V and VIII are the most sensitive to the proteolytic action of plasmin. The plasma levels of other factors, including some that are degraded by plasmin in vitro,<sup>267</sup> usually are normal in fibrinogenolysis, eg, factors VII and IX. Factor XIII deficiency was present in some patients.<sup>116</sup>

Presently available techniques for measuring FDP do not discriminate between fibrinogen degradation products and fibrin degradation products, and both produce similar

impairment of hemostatic functions<sup>153,220</sup> (Fig. 10-8, page 437). In the absence of intravascular coagulation, paracoagulable complexes involving fibrin monomers do not form in plasma; thus, the plasma protamine gelation test is negative in fibrinogenolysis.<sup>223</sup> The serum paracoagulation test is positive because of the presence of FDP. Assays for plasminogen and for the various inhibitors of the fibrinolytic enzyme system are quite time-consuming, and are seldom of critical diagnostic importance. Such special techniques may be useful in monitoring therapy with thrombolytic agents (page 1247).

### Treatment

*Epsilon aminocaproic acid* (EACA) is a specific and potent inhibitor of fibrinolysis and fibrinogenolysis. In low concentrations, it inhibits plasminogen activation competitively, and in high concentrations ( $> 0.06$  M) it inhibits plasmin directly in a noncompetitive manner.<sup>106</sup> The clinical effectiveness of this drug is dramatic in carefully selected patients.<sup>228</sup> Complete inhibition of fibrinolysis requires relatively large doses. EACA should be administered intravenously (0.1 g/kg every six hours)<sup>228</sup> if bleeding is severe. The drug is rapidly absorbed after oral administration, and 1 g/hour following a 5-g loading dose is quite effective. The total dose of this drug should not exceed 30 g in a 24-hour period. Newly developed antifibrinolytic agents<sup>110,147</sup> may be even more effective than EACA, but require more thorough evaluation.

Although the effectiveness of EACA as an antifibrinolytic agent is unquestionable, the indications for its use remain vague and controversial. In view of the difficulty of excluding underlying DIC, it has been recommended that "in doubtful cases" EACA should be used together with heparin or following heparin therapy.<sup>228</sup> Unfortunately, information regarding the efficacy of such concomitant or sequential therapy is very limited.<sup>147</sup>

## Miscellaneous Acquired Coagulation Disorders

Postoperative bleeding is a common and serious problem in patients with polycythemia vera<sup>209</sup> and in those with cyanotic congenital heart disease,<sup>62</sup> but the cause remains poorly understood in both disorders. In patients with *polycythemia vera*, various coagulation abnormalities have been reported, the most common being prolongation of the prothrombin time and deficiency of factor V.<sup>309</sup> Fibrinolysis, thrombocytosis, and platelet dysfunction have been prominent in other patients with this condition. The cause and relative importance of all of these findings remain uncertain. Even more confusing are data pertaining to *cyanotic congenital heart disease*.<sup>300</sup> Reports emphasizing the importance of increased fibrinolytic activity<sup>293,296</sup> appear to be in direct conflict with other accounts in which DIC was implicated.<sup>299,298,301</sup> Still other studies have revealed thrombocytopenia without significant coagulation abnormalities.<sup>302,310</sup>

Minor coagulation abnormalities have been described in association with myelofibrosis, Hodgkin's disease, and other lymphoreticular disorders.<sup>62,158,230</sup> The significance of these findings is difficult to assess, since, in all of these disorders, laboratory abnormalities correlate poorly with the severity of bleeding.

A curious phenomenon, as yet to be explained, is the development of deficiencies of a single factor during the course of an acquired disorder, eg, severe acquired hypoprothrombinemia.<sup>303</sup> Such isolated deficiency of factor X has been well documented in amyloidosis.<sup>99,291,301,308</sup> Deficiency of factors IX<sup>307</sup> and XII<sup>297</sup> has been reported in the nephrotic syndrome, presumably as the result of massive protein loss in the urine. In one patient with Sheehan's syndrome, a selective deficiency of factor IX responded to treatment with corticosteroids and thyroid.<sup>294</sup> An acquired syndrome resembling von Willebrand's disease also has been described.<sup>299a</sup> Mild deficiencies of factors V and VIII may be associated with *massive blood transfu-*

sions,<sup>299,306,311</sup> which also may produce citrate intoxication,<sup>290</sup> and thrombocytopenia (page 1102). Minor coagulation abnormalities have been reported in uremia,<sup>305</sup> but the major cause of bleeding in the uremic patient is platelet dysfunction (page 1129). Many other acquired coagulation abnormalities reported in the older literature are now presumed to have resulted from DIC.

homeostatic control mechanisms may be of pathophysiologic importance in thrombosis. The present discussion is perforce limited to the nature and importance of these alterations, and the mechanisms by which antithrombotic agents affect the platelets and the coagulation factors. No attempt will be made to provide details concerning the pharmacology of the many anticoagulant drugs, or to discuss the pathophysiology and management of specific thromboembolic complications. For an introduction to the vast body of information concerning thrombosis, the reader is referred to several excellent reviews,<sup>42,47,118,128,131,136a,179,196</sup> and books,<sup>83,100,108,139,168,171</sup>

THE term "thrombosis" refers to the formation, from constituents of the blood, of an abnormal mass within the vascular system of a living animal. Thrombosis thus involves the interplay of vascular, cellular, and humoral factors within a flowing stream of blood. It is a kinetic process to be distinguished from the static phenomenon of blood coagulation.

Thrombosis of the veins and arteries, together with complicating embolic phenomena, is perhaps the most important cause of sickness and death in the developed countries of the world at the present time.<sup>82</sup> It is of far greater overall clinical importance than all of the hemorrhagic disorders combined.

There is preliminary evidence that alterations in the hemostatic apparatus and its

### Pathophysiology of Thrombosis

That abnormalities of the vessel wall, alterations of blood flow, and changes in the composition of the blood are the major factors in the pathophysiology of thrombosis was well recognized in the 19th century. The hematologic aspects of thrombosis may still be considered in terms of these three factors, which usually are known as the *triad of Virchow* (Fig. 39-1).

#### Role of the Vessel Wall

*Arterial thrombosis* often is the result of a process that damages the vessel wall, eg, ath-

Fig 39-1 Pathophysiology of thrombosis. Shown are some of the factors implicated in the pathophysiology of arterial thrombosis (left) and venous thrombosis (right). The processes illustrated are highly theoretical.

erosclerosis. It commonly begins with the formation of a tūdus of platelets and fibrin on the vascular surface.<sup>179</sup> This process may be initiated by ADP or a similar chemical mediator that is released from injured vessels,<sup>12,95</sup> or it may result from exposure of collagen fibers in the vessel wall.<sup>7,179</sup> This initiates the processes of platelet adhesion, aggregation, and thrombus formation in much the same manner as it leads to the formation of a normal hemostatic plug (Chapter 9). Neither of these hypotheses explains how arterial thrombi propagate far beyond the site of injured endothelium,<sup>82</sup> and in many forms of arterial thrombosis the pathophysiology is unclear.

In *venous thrombosis*, the vessel wall usually is histologically normal, and factors extrinsic to the vessel appear to have the major pathophysiologic role. An exception to this generalization is direct trauma to or erosion of veins. There is some evidence that fibrinolytic activity in the veins of the legs is subnormal, as compared to that in other veins.<sup>150</sup> A generalized reduction in venous tone may be an important pathophysiologic factor in venous thrombosis in pregnant women, and in women taking oral contraceptives.<sup>72,202</sup>

### Role of Abnormalities of Blood Flow

*Arterial thrombosis* initially occurs under conditions of rapid blood flow, and arterial thrombi are presumably non-occlusive for a time. They usually are composed of a tightly coherent mass of platelets, which contains small amounts of fibrin and a few erythrocytes and leukocytes. These are the classic *white thrombi*, which resemble, in many respects, the normal hemostatic plug (page 396). As arterial thrombi enlarge, progressive or intermittent deposition of new layers of platelets and fibrin produces the characteristic lines of Zahn, and partial or complete obstruction of blood flow may produce a "tail" of red thrombus. Abnormalities of blood flow are of uncertain pathophysiologic significance in arterial thrombosis, although turbulent blood flow and hyperviscosity may be con-

tributory factors in certain forms.<sup>134</sup> The most serious consequences of arterial thrombosis are those caused by vascular occlusion.

*Venous thrombosis* develops under conditions of slow blood flow, and is favored by further retardation and stagnation of flow.<sup>196</sup> Venous thrombi are composed of large amounts of fibrin containing numerous erythrocytes. In this loose, friable mass (*the red thrombus*) the platelets and leukocytes are enmeshed in random fashion. Venous thrombi resemble blood clots formed in vitro; they usually produce significant obstruction to blood flow from the outset, but their most serious consequences are those of embolization.

Studies of clots formed in a thromboviscometer at varying rates of shear,<sup>48</sup> and of serum-induced thrombi in animals,<sup>198</sup> suggest that the differences in the structure of venous and arterial thrombi may be mainly the result of the velocity of blood flow. The many and very complicated *rheologic factors* that may be involved in thrombosis have been reviewed.<sup>71</sup>

The pathophysiologic role of stasis in venous thrombosis is well recognized.<sup>82,184,196</sup> It has been suggested that this is mediated by impairment of mechanisms which normally remove activated coagulation factors from the circulating blood; ie "washout"<sup>45</sup> (page 431), and hepatic clearance (page 432). Additional factors must be involved, however, since marked venous stasis occurs daily in normal persons; eg during dependency of the legs. These additional factors presumably reside in the coagulation mechanism, as discussed below.

### Role of Alterations in the Blood

The role that abnormalities of the hemostatic apparatus play in the pathophysiology of thrombosis remains very poorly understood. Many techniques originally devised for testing the hemostatic functions of platelets and coagulation factors appear to be poorly suited to the study of thrombosis. Moreover, with very few exceptions, thrombosis is a

natural occurrence only in man.<sup>60</sup> As a consequence, some animal models may prove to be irrelevant to the study of thrombosis in man.<sup>47,82</sup>

### Platelets

Thrombosis is a significant, if not the major, clinical feature of certain disorders associated with *thrombocytosis* (page 1103). The pathophysiology of thrombosis in these disorders is obscure. It is probable that an as yet undetermined qualitative abnormality of the platelets is involved. The importance of increased platelet numbers per se is uncertain.<sup>36,118</sup>

Attempts to demonstrate *qualitative abnormalities* of platelet function in patients or animals with various forms of thrombosis, and in patients with various disorders associated with an increased "risk" of thrombosis,<sup>100,193</sup> have resulted in a voluminous literature containing little clear-cut information.<sup>76,132,133</sup> Measurements of platelet aggregation,<sup>25,40,76,141,165</sup> platelet factor 3 (PF-3) availability,<sup>163</sup> and of various biochemical properties of the platelet<sup>139</sup> and the study of platelet thrombi artificially formed in the Chandler tube<sup>6,32,118</sup> have revealed minor or inconsistent abnormalities, most of which are probably nonspecific.<sup>82</sup>

Fatty acids induce platelet aggregation and the release reaction,<sup>92</sup> and are thrombogenic in some animals.<sup>38</sup> Hyperlipidemia in humans<sup>139</sup> and fat feeding in animals may produce an increase in "available" platelet factor 3.<sup>163</sup> In one study in animals, cholesterol feeding was thrombogenic only when thrombocytosis was induced by phlebotomy.<sup>26</sup> The pertinence of these observations to the pathophysiology of human thrombosis is unclear.

Studies of *platelet retention or adhesiveness* have suggested that the platelets may be abnormally "sticky" in patients with active thromboembolism<sup>76,88,98</sup> and in those with various disorders associated with an increased risk of thromboembolic complications, eg, obesity, smoking, hypertension, homocystinuria,<sup>123a</sup> diabetes.<sup>158,193</sup> Increased platelet

"adhesiveness" has been demonstrated more often with the methods of Wright<sup>203</sup> and Hellem<sup>86</sup> than with the Salzman technique.<sup>167</sup> There is evidence in some patients that increased platelet "stickiness" is the result, rather than the cause, of thromboembolic disease.<sup>51,88,97</sup> The abnormalities are slight, in any case, and many studies concerning platelet "stickiness" have been inadequately controlled.

Preliminary evidence would suggest that the *sensitivity of the platelet to ADP* may be significantly increased in various thromboembolic disorders.<sup>76</sup> This abnormality is best demonstrated by measurements of the electrophoretic mobility of the platelets,<sup>79,87</sup> and has been found in patients with ischemic heart disease,<sup>81</sup> persons having peripheral arterial disease,<sup>80</sup> in women who are pregnant and in those taking oral contraceptives,<sup>20</sup> and also in association with multiple sclerosis,<sup>19</sup> various acute illnesses,<sup>79</sup> and following surgical operations. The abnormal sensitivity to ADP apparently is not intrinsic to the platelets, but rather is the result of the presence of an abnormal plasma factor.<sup>82</sup> This factor may be a phospholipase capable of converting low-density lipoproteins, such as lysolecithin, into lecithin.<sup>14,77,128</sup> It is probable that increased platelet stickiness, described above, is an indirect result of increased sensitivity of the platelet to ADP.<sup>87</sup>

It has been suggested that platelet aggregates, formed in the circulating blood, may cause vascular damage and thrombosis following their lodgement on normal vessel walls.<sup>105,132,133</sup> In terms of this hypothesis, vascular injury may be mediated by substances extruded from platelets during the release reaction.<sup>136</sup> Such a process may also underlie the hypothesized role of the platelets in the pathogenesis of atherosclerosis.<sup>133,179</sup> This concept is provocative in that it reverses the traditional cause-effect sequence in the pathophysiology of arterial thrombosis. Nevertheless, it remains largely speculative. Serotonin and other vasoactive substances released from platelets adhering to emboli in the circulation presumably are the major

causes of the immediate vasomotor effects of pulmonary embolism.<sup>136</sup>

### Blood Coagulation

Over a hundred years ago, Troussseau called attention to the high incidence of recurrent and migratory thrombophlebitis in patients with certain carcinomas.<sup>29</sup> In such patients, and in those affected with many other disorders associated with a thromboembolic diathesis, abnormally rapid blood coagulation can be demonstrated by simple but crude tests, such as the determination of clotting time in siliconized tubes or the PTT.<sup>38</sup> The blood of such patients may be unusually resistant to the anticoagulant action of heparin, a phenomenon that may be measured by various heparin "resistance"<sup>191</sup> and "tolerance" tests.<sup>41,73</sup> High levels of various coagulation factors, particularly fibrinogen, factors V, VII, VIII, and X as well as thrombocytosis, have been well documented in the same disorders,<sup>29</sup> and also in pregnancy and in women taking oral contraceptives (page 421). Hereditary disorders associated with a thromboembolic diathesis and marked, selective increases in the plasma levels of factors V<sup>70</sup> and VIII<sup>151</sup> also have been described. These data have led to the concept that a propensity to thrombosis may be the result of *in vivo* hypercoagulability of the blood.

The determinants of the *hypercoagulable state* are poorly defined. There is no evidence that increases in the concentrations of a single coagulation factor, or even of several factors, are thrombogenic *per se*. High levels of several factors may result from processes not associated with an unusual incidence of thrombosis (page 421), such as hyperthyroidism, a disorder in which thrombosis is exceedingly rare.<sup>197</sup>

Studies of *serum-induced thrombosis* in animals<sup>190</sup> provide evidence that the major factor in the hypercoagulable state is low-grade activation of coagulation, rather than increased levels of various coagulation factors. In this animal model,<sup>45,199</sup> the infusion of

small amounts of serum produced the laboratory abnormalities of hypercoagulability. When stasis was superimposed, venous thrombosis consistently developed.<sup>45</sup> The activated forms of factors IX, X, and XI appear to be responsible for the thrombogenic effects of serum.<sup>45,199</sup>

A laboratory picture similar to that described in the hypercoagulable state may also be seen in patients with chronic diffuse intravascular coagulation (DIC) (page 1211). In such patients, the coagulation time and the PTT may be shortened because of the presence of traces of thrombin or other activated coagulation factors. These activated factors affect one-stage but not two-stage assays (page 1220). High levels of factors V and VIII may reflect the presence in the circulation of thrombin-activated forms of these factors (page 429). Pregnancy has been regarded as a "physiologic" form of chronic DIC by critical observers.<sup>111</sup> The effects of oral contraceptives appear to represent a lesser degree of the same process. These considerations, together with a large body of experimental data, lead to the hypothesis that the superficially different conditions of hypercoagulability and DIC may be fundamentally the same in many cases, differing only with respect to rate, magnitude, and the competence of homeostatic processes.

There is no direct evidence which establishes a cause-effect relationship between the laboratory abnormalities of hypercoagulability and the development of thrombosis in man, and it is probable, in many instances, that the laboratory features of the hypercoagulable state are the effects rather than the causes of thromboembolism. It has been suggested that a combination of stasis and low-grade activation of coagulation may be the major pathophysiologic factor in venous thrombosis in humans.<sup>42</sup> The mechanisms leading to activation of coagulation remain obscure.<sup>45</sup> There is little evidence that slow intravascular coagulation is a continuous physiologic process, as was once believed (page 439).

Tissue factor may form complexes with

factors VII and Xa (page 425). It has been suggested that such complexes, when formed in situ on an injured vascular surface, may persistently activate coagulation in the passing blood.<sup>200</sup> Increased levels of phospholipids may accelerate coagulation in vivo.<sup>157</sup> Fatty acids may induce contact activation<sup>121</sup> and may be thrombogenic in animals.<sup>21,38,39</sup> The significance of these phenomena in thrombosis in man is obscure. Minor abnormalities in the fibrinolytic enzyme system also have been demonstrated in association with various forms of thrombosis and some of the "risk" factors.<sup>125,191</sup> In several patients, inhibitors of fibrinolysis were associated with a life-long thromboembolic diathesis.<sup>21,133,137</sup> The activity of the fibrinolytic enzyme system is subnormal in pregnancy, as discussed elsewhere (page 436). The pathophysiologic significance of this observation is uncertain. Low levels of antithrombin III also have been demonstrated in a number of thrombotic disorders, but they may be the result, rather than the cause, of the pathologic state. A hereditary deficiency of antithrombin III was associated with a thromboembolic diathesis in some families.<sup>52</sup>

## Hematologic Methods for the Detection of Thromboembolic Disease

Attempts to develop blood tests that can "anticipate" the development of thrombosis or that can detect occult thromboembolic disease before it is recognized clinically have been largely fruitless.<sup>60,92</sup> None of the many alterations in platelet function and blood coagulation, described above, reliably indicates a "pre-thrombotic" state. Tests for the detection of these alterations may reveal abnormality following the development of thrombosis, but such findings are usually obtained after the disease has been recognized clinically.<sup>86</sup>

Studies of the turnover rate of isotopically labeled fibrinogen<sup>103</sup> and of products of fibrinogen catabolism and complexes formed therefrom (page 436) have yielded more

promising results. Levels of FDP, as determined by the usual techniques (page 1061), may be slightly elevated in the presence of active thrombosis, and usually are significantly elevated in the presence of pulmonary embolism.<sup>201</sup> A study of this family of protein fragments, by the determination of the gel filtration "pattern" of plasma,<sup>67</sup> suggests that a shift toward larger fragments occurs in hypercoagulability and thrombosis, and that the reverse is seen in fibrinolysis and fibrinogenolysis. This phenomenon apparently underlies the positive findings in para-coagulation tests that are frequently observed in association with these disorders.<sup>75</sup> These techniques are as yet imperfect,<sup>67</sup> and their utility in detecting the "pre-thrombotic" state is unproved. They may be valuable, however, in the recognition of occult thrombosis in sites where radiologic and isotopic techniques<sup>107</sup> are not helpful.

## Anticoagulant Therapy

In view of the minimal role played by blood coagulation in the pathogenesis of *arterial thrombosis*, it is not surprising that anticoagulants have proved to be of dubious value in the treatment of patients with this disorder.<sup>126</sup> Despite a few claims to the contrary, the therapeutic effectiveness of either heparin or coumarin-like drugs in arterial thrombosis appears to be attributable to limitation of further extension of the thrombus and the prevention of complicating venous thromboembolism.<sup>82,173,197</sup>

Anticoagulant therapy is clearly of benefit in *venous thrombosis*. Heparin is of proven effectiveness in the treatment of patients with thrombophlebitis and pulmonary embolism,<sup>126,184,197</sup> in the prevention of thromboembolic complications in bedridden patients, eg, those with fractured hips,<sup>109</sup> in carefully selected patients with cerebral embolism, and in some with diffuse intravascular coagulation (page 1222). Coumarin-like drugs are therapeutically useful in most of the patients in whom heparin is effective.<sup>126,184,197</sup> They are quite effective in the prevention of embolic complications in patients with artificial heart

valves and vascular prostheses.<sup>182</sup> The few carefully controlled studies that have been carried out suggest that these drugs are somewhat less effective than heparin; they are of limited value in DIC and in pulmonary embolism. However, they are widely used because they are cheaper than heparin, can be administered orally, and can be used on an outpatient basis.

### Heparin

Heparin is a highly acidic mucopolysaccharide composed of equal amounts of sulfated D-glucosamine and D-glucuronic acid, interlinked by sulfaminic bridges<sup>115</sup> (Table 39-1). Commercially available preparations are mixtures of heparins of several sizes, which range in molecular weight from 6000 to 20,000. Heparins prepared from the tissues of various animals have significantly different properties.<sup>192</sup> The differences between commercially available preparations, however, are of no certain practical significance.<sup>140</sup>

The unit of heparin is defined by biologic techniques in sheep.<sup>115</sup> USP heparin contains at least 120 U/mg; international standard heparin contains exactly 130 U/mg. Since the potency of individual preparations may range as high as 170 U/mg, caution is advised when this drug is prescribed by weight.

Heparin is active only when it is administered parenterally.<sup>115</sup> Its *in vivo* biodegradation proceeds as a first-order reaction with respect to blood heparin concentration.<sup>141</sup> It is degraded by heparinase, a hepatic enzyme. When administered in large doses, heparin appears in the urine in the form of a weakly anticoagulant complex termed "uroheparin."<sup>115</sup>

### Mechanism of Action

Heparin acts directly in the peripheral blood, and does not affect the hepatic biosynthesis or the plasma levels of any coagulation factor (Table 39-1). It combines with a variety of coagulation factors, presumably as the result of its highly negative charge, and thus may interfere with virtually any step in

coagulation.<sup>17,204</sup> In low concentrations, it inhibits the interactions between factors IXa, VIII, and PF-3 (reaction 4, Fig. 10-4, page 424), the "autocatalytic" actions of thrombin (reaction 13), and the action of factor Xa<sup>197</sup> (reaction 7). In higher concentrations, it inhibits the action of thrombin on fibrinogen (reaction 9).

All of the anticoagulant effects of heparin involve a preliminary interaction with plasma proteins, termed the *heparin cofactors*.<sup>1</sup> There is accumulating evidence that the major heparin cofactor is identical to antithrombin III.<sup>17,204</sup> This substance is the major "progressive" antithrombin of normal plasma, and also is an inhibitor of factor Xa.

Heparin inhibits certain platelet functions including the release of serotonin. This effect may be of therapeutic importance in minimizing the vasomotor sequelae of pulmonary embolism.<sup>164,185,186,198</sup> Heparin also may facilitate fibrinolysis, an effect that may be mediated by its lipolytic action,<sup>113</sup> to be discussed below. The physiologic or therapeutic significance of this phenomenon is uncertain.

There is no definite evidence that heparin normally is present in the blood, or that it acts as a physiologic anticoagulant. Very small amounts of this drug activate *plasma lipoprotein lipase* (heparin "clearing" factor), an enzyme involved in the lysis of triglycerides in chylomicra.<sup>115</sup> The physiologic importance of this action of heparin also is obscure. Several commonly used drugs interfere with the action of heparin (Table 39-1).<sup>149</sup> This anticoagulant does not cross the placenta.<sup>63</sup>

### Regimens

Although heparin has been used therapeutically for more than 30 years, there is no general agreement regarding preferred or optimal treatment schedules. The regimens summarized in Table 39-1 are those usually recommended for the treatment of patients with uncomplicated thrombosis.<sup>50,115,184</sup> It is generally agreed that higher doses than those summarized in Table 39-1 are needed early

†More detailed laboratory control may be desirable in many cases

‡Evidence is preliminary; controlled trials on large numbers of patients are not as yet available

in the course of acute pulmonary embolism,<sup>181</sup> eg, 10,000 to 15,000 U intravenously every four hours.<sup>69</sup> For prophylaxis, much smaller doses have proved effective, eg, 5000 U subcutaneously every eight hours.<sup>69</sup> The subcutaneous route of administration and various repository forms of heparin<sup>115</sup> may be suitable for prophylaxis, but are not recommended for the treatment of patients with major thrombosis or pulmonary embolism. The intramuscular route of administration is not recommended because of the frequency of complicating hematomas.<sup>129</sup> The dose of heparin should be reduced in patients with thrombocytopenia.<sup>83</sup> Details will be found elsewhere concerning the use of heparin in extracorporeal circulatory devices and in hemodialysis.<sup>83,165</sup> The utility of heparin for *in vitro* blood preservation is discussed on page 8.

### Laboratory Control

There is no entirely suitable method for monitoring the *in vivo* effects of heparin.<sup>153</sup> For many years the whole blood coagulation time has been used for this purpose. When heparin is administered intravenously on an intermittent schedule, the coagulation time, as determined prior to the next dose, should be kept within one and one-half to three times normal or baseline values. The inaccuracies and limitations of the coagulation time as a screening test for bleeding disorders were discussed on page 1057; these apply equally to its use in controlling heparin therapy. Several other simple coagulation tests are useful in monitoring the effects of heparin. They are, in order of decreasing sensitivity, the plasma thrombin time, the partial thromboplastin time (PTT), and the prothrombin time. The last-named test is relatively insensitive to the action of heparin, but may be valuable as a rough index of heparin effects,<sup>83</sup> eg, in neutralizing heparin following surgical procedures involving extracorporeal circulation.

Many laboratories now employ the *activated PTT* for monitoring of heparin therapy.<sup>37,180,181,206</sup> The results of this test cor-

relate closely with the coagulation time at low heparin concentrations. However, the PTT is virtually infinite at high heparin concentrations, a fact which limits its usefulness in monitoring peak levels of heparin.<sup>119</sup> Modifications of the PTT that employ diluted plasma,<sup>119</sup> and simplified methods for the direct assay of heparin concentrations in plasma,<sup>204a</sup> also have been proposed for the control of heparin therapy.

It is probable that the value of frequent monitoring of the effects of heparin, in terms of preventing hemorrhagic complications,<sup>11,181</sup> has been overemphasized. In one study,<sup>153</sup> none of several monitoring techniques, including specific heparin assays, was correlated with the development of bleeding complications in patients receiving this drug. The frequency of bleeding complications appears to be little, if at all, greater among patients in whom no monitoring techniques are employed,<sup>11</sup> or in those receiving high as distinguished from low doses of the drug.

It is well known, however, that heparin requirements vary greatly,<sup>118</sup> and may change during the course of an illness. Large doses may be required in the presence of an active thrombotic lesion; in some patients with massive thromboembolic lesions, marked "heparin resistance" has been noted.<sup>153</sup> Heparin requirements also may diminish rapidly as the thrombotic lesions resolve. It is probable that a daily estimate of the anticoagulant effects of heparin, as provided by the PTT, for example, should be routinely obtained to prevent a progressive build-up of the *in vivo* concentrations of this drug, and also to make certain that the patient is receiving a sufficient amount.<sup>151</sup>

### Complications

Urticaria, fever, transient thrombocytopenia, and other minor adverse effects<sup>62,74,164</sup> have been described in association with heparin administration, but the major complication attending the use of this drug is hemorrhage. The most common hemorrhagic manifestations are ecchymoses at venipuncture sites, and exacerbation of latent hemor-

rhagic lesions, eg, duodenal ulcers. More serious hemorrhagic manifestations have been described,<sup>84</sup> particularly if aspirin or related drugs have been administered together with heparin.<sup>184</sup> They presumably are the result of the combined effects of heparin and impaired platelet function. A similar phenomenon may explain the high incidence of hemorrhagic complications in association with heparin therapy which has been reported in patients with thrombocytopenia<sup>83</sup> and uremia.

Postoperative and post-traumatic hemorrhage may be serious in patients receiving heparin. Intramuscular injections may produce large hematomas, and when given in the thigh or buttocks may produce retroperitoneal hematomas.<sup>129</sup> The incidence of bleeding complications associated with heparin is unaccountably high in postmenopausal women.<sup>104</sup>

In the treatment of bleeding that may complicate heparin therapy, discontinuing the use of the drug is generally all that is required because of the rapidity with which it is normally degraded. If rapid reversal of the effects of heparin is required, *protamine* is an effective and specific antidote. This agent is a strongly cationic protein, which neutralizes the acidic charge on the heparin molecule.<sup>115</sup> Methods for calculating the required dose have been described,<sup>83,168</sup> but unless the heparin level is very high, a single dose of 50 mg of protamine sulfate given intravenously at a slow rate usually is sufficient.<sup>83,168</sup> Protamine neutralization tests<sup>49,83,168</sup> are very time-consuming, but provide a means of determining the exact amount of protamine required. Such tests are seldom required, and empiric neutralization of heparin has proved safe and effective even following major operations on the heart and lungs. Protamine in great excess may act as an anticoagulant, but this action very rarely presents a significant problem.

*Heparin "rebound"* usually refers to the reappearance of heparin in the circulation, following its apparent neutralization by protamine. This phenomenon usually is seen following the use of extracorporeal cir-

culatory devices, and is poorly understood.<sup>68,73a,168</sup>

### Coumarin and Indanedione Anticoagulants

All of the numerous synthetic and natural compounds that antagonize the biosynthesis of the vitamin K-dependent coagulation factors are derivatives of two basic chemical structures, namely, the 4-hydroxy coumarins and the 1,3-indanediones<sup>115</sup> (Table 39-1). The anticoagulant action of all of these compounds is the same; they differ in terms of pharmacologic features such as the rate and extent of their absorption, or the onset and duration of their action. They are absorbed from the gut, bound almost entirely to albumin and are carried in the plasma in this form. They are hydroxylated by the hepatic cells at a constant rate, and are excreted in the hydroxylated form in the urine.<sup>115</sup> The rate of biotransformation varies greatly from individual to individual.<sup>147</sup> The coumarin-like drugs cross the placenta, an attribute of clinical significance<sup>90</sup> (page 1203).

### Mechanism of Action

The coumarin and indanedione drugs do not act in the circulation but, rather, in the liver, where they impair the synthesis of the four vitamin K-dependent coagulation factors, ie, prothrombin, factors VII, IX, and X.<sup>152</sup> The biochemical mode of action of the coumarins is poorly understood. It has been suggested that they may act on two different receptors,<sup>115</sup> upon processes that metabolize vitamin K<sup>13,43,123</sup> or those that transport this vitamin across the cell membrane.<sup>50,115</sup> Although many of these drugs bear a structural resemblance to vitamin K, they do not act by simple metabolite-antimetabolite competition.<sup>3,115</sup> They lead to the production of qualitatively abnormal congeners of the four coagulation factors,<sup>40a</sup> as discussed on page 414, and there is evidence that, as in vitamin K deficiency, they impair the final synthetic step that transforms a common precursor into the various factors (Fig. 10-2, page 415).

There is a considerable lag between peak plasma levels of the coumarin-like drugs and the maximal prolongation of the prothrombin time. This represents the time required for the coagulation factors in the circulation to disappear. The plasma levels of the four factors fall in a sequence consistent with their *in vivo* survival times (Chapter 10), namely, factor VII the most rapidly, followed by factors IX, X, and prothrombin in that order.<sup>110</sup> The clinical effectiveness of the coumarin anticoagulants is mainly the result of reduction of the levels of factors IX and X.<sup>41</sup>

### Factors That Modify the Action of Coumarin Anticoagulants

Many commonly used drugs (Table 39-1) interact with the coumarin anticoagulants. They may act on any of the various mechanisms involved in the absorption, transport, biotransformation, and excretion of these anticoagulants.<sup>43,112,116</sup> Those of one group, eg, barbiturates, antagonize the action of the coumarins.<sup>112</sup> They produce coumarin "resistance," and may lead to overdosage when they are withdrawn. Other drugs, such as the salicylates and phenylbutazone, potentiate the action of the coumarins. In very large doses, salicylates have a coumarin-like effect, but alone rarely produce bleeding. Broad-spectrum antibiotics and nonabsorbable sulfonamides antagonize vitamin K synthesis by gut bacteria, but there is little evidence that this alone is ever of practical significance in facilitating the action of the coumarins.<sup>112</sup> Coumarins may greatly potentiate the actions of dilantin, tolbutamide, and chlorpropanide, but the effects of these drugs in potentiating the action of the coumarins appear to be minor and of uncertain clinical significance.<sup>112</sup> *In vitro* experiments and studies in animals<sup>112</sup> suggest that a large number of other drugs may interact with the coumarins.

The physician should be well aware of the many drugs that can interact with the coumarin anticoagulants. Such interactions are a common cause of erratic and inadequate anticoagulation or overdosage attended with bleeding, or both.

Many other physiologic factors and pathologic processes modify the effects of coumarin drugs.<sup>3,115</sup> Especially important among these are the functional efficiency of the liver<sup>30</sup> and the dietary intake of vitamin K.<sup>188</sup> Infants are unusually sensitive to the action of coumarin-like drugs. Any of the factors that increase the levels of the vitamin K-dependent coagulation factors (page 421) may antagonize the coumarin anticoagulants. In two families virtually absolute resistance to coumarin-like drugs was inherited as an autosomal dominant trait.<sup>145</sup>

### Regimens

Because of a relatively high incidence of adverse reactions, the indanediones have been largely supplanted by various coumarin derivatives, among which warfarin (Coumadin) and bishydroxycoumarin (Dicumarol) are by far the most widely used (Table 39-1). Therapeutic regimens for the many other oral anticoagulants are described elsewhere.<sup>49,50,113</sup>

Following the administration of warfarin or bishydroxycoumarin, the prothrombin time is maximally prolonged in from 36 to 72 hours.<sup>115</sup> However, the antithrombotic action of both of these drugs apparently is not maximal until the plasma levels of factors IX and X are significantly depressed. This may require several days. Consequently, the administration of 10 to 15 mg of warfarin daily until the prothrombin time is within the therapeutic range may be therapeutically as effective and less dangerous<sup>43</sup> than traditional regimens which employ larger initial loading doses.<sup>43,116</sup>

### Laboratory Control

The plasma prothrombin time is sensitive to three of the four vitamin K-dependent coagulation factors. Consequently this test, or a modification thereof, is the preferred method of monitoring the effects of coumarin-like drugs in the laboratory.

A large number of modified thrombo-

plastins, and technical modifications of Quick's original one-stage prothrombin time (page 1056), have been advocated by various authorities. The advantages claimed for these techniques include greater overall sensitivity and precision,<sup>49</sup> and greater or lesser sensitivity to the various coagulation factors. Modifications that make the test less sensitive to the levels of factor V (P and P, Thrombotest) may offer some advantage in the determination of the prothrombin time of mailed or stored specimens. The prothrombin time may be performed on capillary blood with Thrombotest.<sup>49</sup> With these exceptions, however, these modifications probably offer no advantages over the standard one-stage prothrombin time, when it is expertly performed with a well-standardized thromboplastin<sup>116</sup> on a carefully collected blood specimen. In patients receiving coumarin and indanedione drugs, the "therapeutic range" for the prothrombin time, as determined with the usual techniques, is from 1.6 to 2.5 times<sup>49,50</sup> control values.

When it is desired to switch from heparin to one of the coumarin anticoagulants, the two drugs must be given concomitantly for a time, usually for three to five days. During this period, the coagulation time is still a valid indicator of heparin effect, because it is little affected by coumarin-like drugs. However, the prothrombin time is meaningless as an indicator of coumarin effect, because it is prolonged by heparin. The PTT is affected by both coumarin and heparin.

### Complications

Bleeding due to the coumarin drugs is a common complication. Virtually all hemorrhagic manifestations have been encountered, including some serious ones,<sup>49,50,117</sup> eg, bleeding into the central nervous system. Hematuria and gastrointestinal bleeding occur frequently, but are found to originate from localized organic lesions with surprising frequency. Gastrointestinal bleeding from peptic ulcers is one of the most common causes of fatal hemorrhage. As with heparin, the assumption that bleeding can always be

avoided by careful regulation of the dosage of the coumarin drugs is not entirely justified, since, in some patients, bleeding develops when the prothrombin time is within the therapeutic range.

Bleeding usually is minimal following surgical procedures or injuries in patients receiving the coumarin drugs. It is probable that use of these drugs need not be discontinued when common surgical procedures are performed.<sup>166</sup> Aspirin is contraindicated in patients receiving coumarin-like drugs, since inhibition of platelet function may provoke hemorrhage.

Bleeding due to the surreptitious self-administration of coumarin drugs is not uncommon.<sup>4,23</sup> This problem (the *dicoumarol "eaters" or malingers*) is most common in women, and in medical or paramedical personnel. Drug ingestion usually is denied, but puzzling and fluctuating laboratory abnormalities should arouse suspicion. Significant psychiatric abnormalities are present in some patients, but in others protracted self-treatment of resolved or imagined thromboembolic disorders is responsible. The parenteral administration of large doses of vitamin K and the chemical determination of plasma coumarin levels<sup>9</sup> may be required for diagnosis.

The administration of vitamin K usually is advisable in the treatment of hemorrhagic complications in patients who are receiving the coumarin drugs, because of the relatively long duration of action of these agents. The response to vitamin K is more variable than is commonly realized.<sup>205</sup> The administration of 25 mg of vitamin K<sub>1</sub> usually restores the prothrombin time to normal within 24 hours. Larger doses (50 mg) may be required to counteract the effects of longer-acting drugs; in severe toxicity, two to three doses of vitamin K<sub>1</sub> may be required. The absence of a response to vitamin K suggests a complicating process, eg, liver disease, diffuse intravascular coagulation (Chapter 38).

*Skin necrosis* is a rare but dramatic complication of coumarin therapy. These lesions apparently represent a unique form of vascular purpura, and usually develop during the first week of treatment. They are most com-

mon in women, and usually involve the legs, breasts, and external genitalia. They may be very painful,<sup>189</sup> but seldom produce serious sequelae. A symmetrical, purplish, painful discoloration of the toes also may develop as a consequence of coumarin therapy.<sup>59</sup> The pathophysiology of this manifestation is obscure.

## Miscellaneous Antithrombotic Agents

### Therapeutic Defibrination

In 1963, Reid and associates<sup>162</sup> observed that envenomation by the Malayan pit viper (*Ancistrodon rhodostoma*) produces total afibrinogenemia with incoagulable blood, in the absence of significant hemorrhage or vascular occlusion. Investigation of this remarkable phenomenon has led to the development of a unique form of antithrombotic therapy which employs an enzyme purified from the venom of this snake. This agent (*ancrod*, *Arvin*) is capable of rapidly removing fibrinogen from the circulating blood, without producing significant alterations in other coagulation factors or the platelets (Table 39-1).<sup>56</sup> It is a potentially useful therapeutic agent, but at present remains in the investigational stage.<sup>187</sup>

### Mechanism of Action

As purified from the crude venom, ancrod is a thrombin-like proteolytic enzyme which has a molecular weight of approximately 30,000 and contains 20% carbohydrate.<sup>56</sup> It converts fibrinogen into an abnormal soluble fibrin polymer.<sup>10,74</sup> Much of this fibrin remains in solution, but "microclots" also are formed<sup>177</sup>; both forms are removed from the circulation by the reticuloendothelial system<sup>55</sup> and as the result of rapid fibrinolysis.<sup>55,58</sup> Crude venom contains a second enzyme capable of lysing circulating fibrinogen,<sup>160</sup> but this is not present in ancrod.

The proteolytic action of ancrod on fibrino-

gen results in the removal of the fibrinopeptides A and several abnormal basic peptides,<sup>156</sup> but peptide B is not removed.<sup>55,93</sup> It does not activate factor XIII, which may explain the susceptibility to fibrinolysis of the fibrin produced by ancrod.<sup>156</sup>

The active principle in ancrod is rapidly degraded in vivo, probably by the reticuloendothelial system<sup>161</sup>; it also is inactivated by alpha-2 macroglobulin and antithrombin III (page 431).<sup>154</sup> A specific antivenom that rapidly reverses the effects of this agent in vivo has been developed.<sup>187</sup>

### Efficacy

Studies of experimental thrombosis in animals have suggested that ancrod is capable of preventing venous thrombosis<sup>122</sup> and favorably affects pulmonary embolism.<sup>143</sup> Studies in animals suggesting that this enzyme may accelerate the removal of preformed thrombi<sup>122</sup> could not be confirmed in human subjects.<sup>109,159</sup> In one animal model, ancrod treatment significantly reduced the incidence of arterial thrombosis.<sup>187</sup>

Preliminary clinical trials in man have demonstrated encouraging therapeutic responses in venous thrombosis,<sup>15,159,174</sup> retinal vein thrombosis,<sup>22</sup> and long-standing priapism.<sup>14</sup> There is little evidence, however, that ancrod is any more effective than heparin in the treatment of most of these disorders.<sup>109</sup> Carefully controlled studies in large groups of patients have yet to be reported.

Therapeutic defibrination with ancrod is remarkably free of adverse effects.<sup>187</sup> The only significant side effect encountered in experimental animals was disseminated microthrombosis, a complication that developed only when the enzyme was administered too rapidly.<sup>7,121</sup> In man, spontaneous hemorrhage is very rare, but postoperative bleeding has been described.<sup>174</sup> Microangiopathic hemolytic anemia, presumably due to the effects of intravascular fibrin deposits,<sup>174</sup> has been noted in an occasional patient, as has defective wound healing.<sup>94,174</sup> Ancrod is antigenic,<sup>15,155,174</sup> a drawback that may somewhat limit its overall usefulness.

## Thrombolytic Therapy

In thrombolytic therapy, the endogenous fibrinolytic enzyme system is activated by the administration of plasminogen activators, with the object of inducing or accelerating the lysis of a preformed thrombus<sup>175</sup> (Table 39-1). Thrombolytic therapy is thus directed at the thrombus *per se*, rather than at the causes of thrombosis.<sup>61</sup>

### Mechanism of Action

The only agents presently available for thrombolytic therapy are streptokinase and urokinase. Synthetic agents<sup>61</sup> and enzymes derived from plants<sup>90</sup> are presently in the developmental stage. Streptokinase is antigenic,<sup>65</sup> and its administration produces fever and other adverse effects. Urokinase of high purity avoids these problems, but is expensive and in very short supply, even for investigative trials.

The infusion of urokinase and streptokinase in full therapeutic doses results in the prompt appearance of plasminogen activators in the circulating blood, and the presence of variable amounts of free plasmin (Fig. 10-7, page 433). This leads to fibrinolysis, and to fibrinogenolysis of variable degree. The mechanisms by which this occurs, and the many laboratory abnormalities that may result, are described in detail in Chapters 10 (page 432) and 38 (page 1244). A considerable excess of both streptokinase and urokinase must be administered to overcome plasma inhibitors; the "thrombolytic state" can then be maintained by the administration of smaller maintenance doses of either enzyme.<sup>124</sup> The dosage of both agents must be individualized, since the responses of individual patients vary greatly. With most regimens, plasminogen depletion occurs rapidly.

Antifibrinolytic agents such as EACA and tranexamic acid are potent and effective antidotes to the effects of thrombolytic agents.

### Efficacy

The evidence that thrombolytic therapy is capable of lysing thrombi in animals without undue hazard of hemorrhage is now convincing.<sup>124,175</sup> This mode of therapy has been thoroughly evaluated in only a small number of patients, although there are many reports of uncontrolled trials, and many others in which benefit was claimed even though only homeopathic doses of thrombolytic agents were administered. The most clear-cut evidence for the clinical effectiveness of thrombolytic therapy has been obtained in patients with peripheral arterial thrombosis.<sup>99,114,124</sup> In patients with thrombosis of leg veins<sup>184</sup> and in those with pulmonary embolism,<sup>172,184</sup> thrombolytic therapy accelerated the recanalization of affected vessels, an effect not observed in heparin-treated controls. It is uncertain, however, whether the overall therapeutic effectiveness of streptokinase and urokinase was significantly greater than that of heparin.<sup>102,127,183,184</sup> In myocardial infarction, a slight but significant reduction in mortality was produced by thrombolytic therapy.<sup>5,191</sup>

The efficacy of thrombolytic therapy is diminished if it is not given early, since older thrombi are resistant to lysis.<sup>67</sup> Thrombi that form after plasminogen has been depleted also are resistant to further lysis, and for this reason anticoagulants usually are administered following the cessation of thrombolytic therapy.<sup>175</sup>

The results of preliminary studies of thrombolytic therapy have been encouraging; the enzymes, streptokinase and urokinase, are among the few presently available therapeutic agents that offer promise in the treatment of arterial thrombosis.<sup>57</sup> Additional large, carefully controlled clinical trials of thrombolytic agents are certainly indicated.<sup>175</sup>

### Drugs That Impair Platelet Function

Theoretically, agents that impair platelet function might be therapeutically effective in

the treatment for arterial thrombosis (Table 39-1). An intensive study of the antithrombotic properties of the numerous compounds, discussed in Chapter 35, that inhibit platelet functions in vitro is presently underway.<sup>195</sup>

*Dipyridamole*, a drug initially marketed as a coronary vasodilator, is a potent inhibitor of the platelet release reaction (page 394). It is effective in inhibiting experimental arterial thrombosis in rabbits<sup>51</sup> and rats,<sup>46</sup> and markedly reduced the incidence of thromboembolic complications in patients with prosthetic heart valves.<sup>51,182</sup> It has proved ineffective as an antithrombotic agent under other circumstances.<sup>2,28,170,195</sup> Analogs of this compound are currently under intensive study.<sup>53</sup>

*Aspirin*, in very small doses, is a potent inhibitor of the platelet release reaction. Studies in animals suggest that this drug has a significant antithrombotic effect,<sup>47,195</sup> and preliminary trials suggest that it may be useful in the prevention of ischemic heart disease in man.<sup>20a,53a</sup> Other therapeutic trials in man have been disappointing.<sup>142,144</sup> Aspirin apparently is not therapeutically beneficial in preventing venous thrombosis in patients with hip fractures<sup>201</sup> or in the treatment of patients with leg vein thrombosis.<sup>104</sup> Large cooperative studies of the effects of this drug in arterial thrombosis, such as that involved in transient ischemic attacks and ischemic heart disease, are underway.

*Dextran* of low molecular weight has been shown to inhibit platelet aggregation and the release reaction in vitro. It also may have an "antiadhesive" effect on vascular surfaces, and a weak heparin-like effect when given in high concentrations.<sup>49</sup> This polymer appeared to prevent thrombosis of the leg veins in some clinical trials,<sup>85</sup> but not in others.<sup>27,170,181</sup> Evidence that it is effective in the prevention or treatment of thromboembolic disorders is less convincing than is the case with either heparin or the coumarins. Despite this fact, dextran has gained surprisingly widespread acceptance in the treatment of patients with thrombosis.

# Part V

## Disorders Characterized By Adenopathy, Splenomegaly, and/or Abnormalities of Leukocytes or Immunoglobulins

In the following chapters, disorders which primarily involve the immune system (lymphocytes, lymph nodes, plasma cells, and immunoglobulins) and the mobile phagocytic system (neutrophils, eosinophils, and monocytes) will be considered. Conditions leading to detectable abnormalities of these systems may be self-limited and benign or they may be serious. As with Disorders of the Red Cells (Part III) and Disorders of Platelets (Part IV), the cellular disorders to be discussed here can be classified as abnormalities of cellular excess, cellular deficiency, or intrinsic cellular abnormality. Cellular excess or deficiency is detected by finding enlarged lymph nodes or splenomegaly on physical examination or increased or decreased concentrations of leukocytes in the blood or bone marrow. Intrinsic cellular abnormality may be accompanied by detectable morphologic changes or its diagnosis may require tests of cell function or determination of biochemical composition. As in the other cellular systems (Parts III and IV), discussion of the specific types of abnormality and disease affecting the immunocytic and phagocytic systems will follow consideration of the overall diagnostic approach to the patient with these conditions.

## SECTION 1: *Approach to Disorders of the Phagocytic and/or Lymphatic Systems*

This section presents an *orderly* approach to diagnosis of disorders characterized by lymphadenopathy, splenomegaly, and/or abnormalities of leukocytes or immunoglobulins. These disorders may take the form of (1) reactions to other diseases (changes in blood leukocytes and/or enlarged lymphoid tissue), (2) neoplastic diseases (leukemias, lymphomas, and immunoglobulin-producing tumors), and (3) idiopathic or inherited diseases due to defective phagocytosis or antibody production.

### *Diagnostic Steps in the Evaluation of the Patient with Abnormalities of Leukocytes or Immunoglobulins, or Lymphadenopathy, Splenomegaly, Fever of Unknown Origin, or Recurrent Infection*

Examination of the Blood  
Bone Marrow Examination  
Lymph Node Examination  
Examination of the Spleen  
Fever of Unknown Origin  
Recurrent Infections

THE patient may have no symptoms referable to a disorder of the phagocytic or immune systems or there may be signs and symptoms suggesting infection. Other common presenting complaints, especially in patients with neoplastic disease, include fever without evident infection, fatigue, enlarged lymph nodes or other masses, abnormal bleeding, weight loss, pain in bones and joints, and

generalized itching. Suspicion that one is dealing with such a disorder may be raised during the course of routine examination, or during evaluation of unrelated disorders, by the detection of lymphadenopathy, splenomegaly, or hilar or mediastinal masses. In other instances, blood examination discloses leukocyte abnormalities such as leukopenia, leukocytosis or abnormal cells, anemia and/or platelet abnormalities, or altered levels of immunoglobulins.

A detailed history should be obtained and a thorough physical examination made. Chest x ray, urinalysis, blood examination (including study of red cells, white cells, platelets, and the blood smear), marrow examination, lymph node biopsy, liver biopsy, splenec-

tomy, and paper electrophoresis and immunoelectrophoresis of serum or urinary proteins may be necessary. In addition, evaluation of delayed hypersensitivity and tests of neutrophil function may be required. Obviously not all or even most of these tests and surgical procedures are indicated in each patient who has the symptoms described above. Rather, a logical sequence of studies is undertaken in each patient, tailored to the particular findings. A diagrammatic summary of diagnostic sequences is shown in Figure 40-1.

## Examination of the Blood

The blood may be entirely normal in some patients with lymphoma, myeloma, immune deficiency, neutrophil dysfunction, or a variety of other syndromes associated with lymphadenopathy or splenomegaly. Anemia, when present, usually is normochromic and normocytic. However, some patients with "preleukemic" myeloblastic leukemia (Chapter 47) or with multiple myeloma (Chapter 52) have anemia but no other symptoms. Anemia of unknown origin should lead to marrow examination as well as serum and urine protein electrophoresis.

Thrombocytopenia and/or thrombocytosis with no other signs, symptoms, or blood findings suggesting the diseases under consideration is extremely rare, having been described in only a few patients with "preleukemic" myeloblastic leukemia (Chapter 47). However, thrombocytopenia commonly accompanies other blood changes in diseases such as the acute leukemias (Chapter 47) as does thrombocytosis in chronic myelocytic leukemia (Chapter 48).

Changes in blood leukocytes, if present, may, in themselves, provide the diagnosis, as in the leukemias, may strongly suggest the correct diagnosis, or may be nonspecific but still indicative of certain specific conditions. Certain rare diseases associated with frequent infection can be recognized by morphologic changes in leukocytes (eg, Chediak-Higashi syndrome,<sup>5</sup> Chapter 42).

Leukocyte changes in the blood of patients with acute leukemia (Chapter 47) provide the

diagnosis in more than half such patients and strongly suggest it in virtually all. In approximately 60% the smear confirms the diagnosis by virtue of the presence of a large proportion of immature cells, whether or not there is an increased leukocyte count.<sup>6</sup> Blasts are easily demonstrable in blood smears of more than 90% of patients and, even in patients in whom few blasts are present in the blood smear, anemia, thrombocytopenia, neutropenia, or combinations of these changes suggest acute leukemia. In almost all such patients, bone-marrow aspiration proves diagnostic.

More than  $10.0 \times 10^9$  small lymphocytes/l of blood is usually indicative of chronic lymphocytic leukemia, especially if the patient is middle-aged or elderly, since more than a slight elevation in the number of cells is unusual in other diseases (Chapters 41 and 49). Characteristic signs and symptoms of chronic lymphocytic leukemia may be absent at a time when a diagnosis can be made from examination of a blood smear (Chapter 49).

The presence of chronic myelocytic leukemia (Chapter 48) may be strongly considered on the basis of a blood smear. However, the diagnosis depends upon other findings in addition to neutrophilia. For instance, in the presence of *all* of the following a firm diagnosis can be reached without other considerations: (1) symptoms limited to fatigue, bone pain, left upper-quadrant mass or fullness; (2) sternal tenderness and splenomegaly revealed by physical examination, without other abnormalities excepting pallor or, rarely, tenderness in bones other than the sternum; (3) more than  $100.0 \times 10^9$  leukocytes/l of blood with abundant mature neutrophils and myelocytes with lesser numbers of blasts and promyelocytes and with increased basophils and eosinophils; (4) thrombocytosis and normocytic, normochromic red cells with or without anemia. With any slightly atypical features, a "leukemoid reaction" (Chapter 41), usually due to infection or carcinoma, or disorders such as idiopathic myelofibrosis (Chapter 57), must be considered. However, if cytogenetic examination of the marrow reveals the Philadelphia chromo-

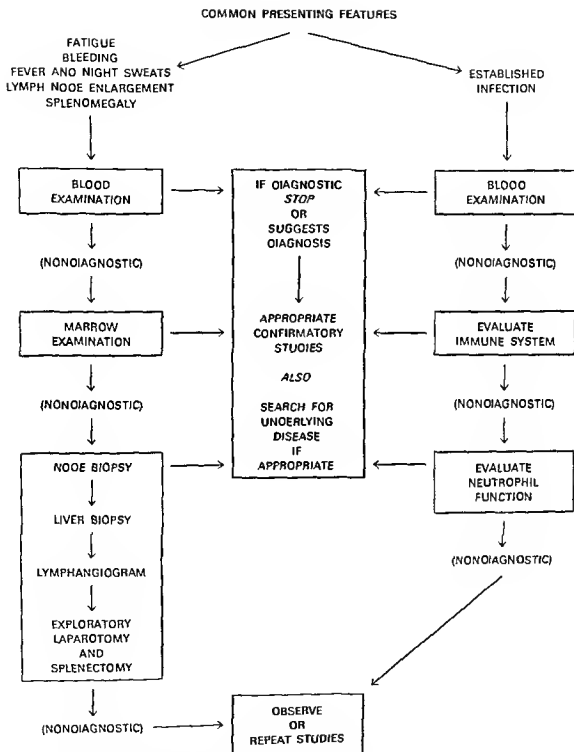

Fig 40-1 Diagnostic steps in diseases of the phagocytic and immune systems

some (Chapter 46), a reasonably firm diagnosis of chronic myelocytic leukemia can be made.

Patients with multiple myeloma may have a few plasma cells in the blood and, occasionally, large numbers (plasma cell leukemia, Chapter 52). Such patients almost invariably have symptoms and signs of the disease. A few cells resembling plasma cells may be observed in blood smears of patients with infectious mononucleosis or other viral infections. Plasma cells also are seen in the blood of persons recovering from bacterial infections or having allergic reactions, especially serum sickness.

The presence of other rare diseases such as systemic mastocytosis (Chapter 47) can be strongly suspected when large numbers of mast cells are seen on blood smears.

Blood leukocyte changes requiring diagnostic consideration which are secondary to a variety of diseases (Chapters 41 and 43) usually consist of neutrophilia, eosinophilia, monocytosis, or normal- or abnormal-appearing lymphocytes. If the leukocyte change is appropriate to the clinical situation, eg, pneumococcal pneumonia with  $200 \times 10^9$  segmented and band form neutrophils/l, the obvious disease should be treated and the blood reevaluated when this has been accomplished.

The causes of unexplained neutrophilia are considered in Chapter 41 as are those for persistent eosinophilia and monocytosis.

Abnormal-appearing lymphocytes such as those seen in infectious mononucleosis must be distinguished from lymphoblasts. This distinction is easily made by the experienced morphologist<sup>12</sup> (Chapter 43). The presence of such cells even in the absence of signs and symptoms characteristic of the disease should raise the question of infectious mononucleosis and appropriate heterophil antibody tests should be carried out (Chapter 43). Such cells also are observed in a variety of viral and protozoal infections such as measles, infectious hepatitis, and toxoplasmosis. If the reaction to the heterophil test is negative, serologic studies for the detection of such diseases should be performed. If no diagnosis is es-

tablished, patience and further observation are advisable. Lymph node biopsy and marrow examination may or may not reveal similar abnormal cells, but they will provide little diagnostic information beyond that obtained from the blood smear.

Neutropenia may provide an explanation for the presence of infection (page 1263). This finding demands consideration of its various causes (Chapter 41). Lymphopenia is produced by a wide variety of causes but is usually a transient phenomenon (Chapter 41). Persistent lymphopenia suggests a defect in cellular immunity such as that present in Hodgkin's disease (Chapter 50).

## Bone Marrow Examination

If a diagnosis is not established by examining the blood, bone marrow examination may prove helpful. If lymphoma or any granulomatous or carcinomatous process or myelofibrosis is under consideration, needle biopsy should be performed in addition to aspiration (Chapter 2). As noted in the previous section, confirmation of a suspected diagnosis of acute leukemia or of myeloma is obtained by means of marrow aspiration. Except for cytogenetic studies, marrow examination provides no more diagnostic information than does blood examination in the chronic leukemias.

A diagnosis of lymphoma may sometimes be established from examination of the bone marrow, especially if biopsy is performed (Chapter 51). Evidence of disease in the marrow was found in 30% of patients with lymphocytic lymphoma, 26% of patients with giant follicle lymphoma, and 19% of patients with reticulum cell (histiocytic) lymphoma.<sup>29</sup> However, marrow involvement was found in fewer than 10% of patients with Hodgkin's disease.<sup>8</sup> Biopsy of bone marrow also is useful in evaluating the extent of lymphomatous disease (staging, Chapters 50 and 51) once the diagnosis has been confirmed. Thus, marrow examination can be justified in any patient suspected of having a lymphoma and in a minority of the patients this examination will yield a definitive diagnosis.

If patients complain of bone pain, the bone marrow should always be examined whether or not bone lesions have been demonstrated radiographically. However, multiple myeloma is occasionally quite focal in nature and in such instances plasmacytosis may not be detected in the area of marrow which is examined. Marrow aspiration or biopsy of a site suggested by radiography should then be considered. Serum protein electrophoresis and a test for Bence Jones protein in the urine should also be routinely performed in such patients. Only some 2% of patients with myeloma have neither a "spike" on electrophoresis of serum proteins nor Bence Jones protein in the urine (Chapter 52).<sup>28</sup>

The indications for marrow examination in the evaluation of the patient with fever or infection are considered later in this chapter (page 1263).

## Lymph Node Examination

This section is concerned with the evaluation of the patient with palpable or visible enlargement of cervical, supraclavicular, axillary, inguinal, mediastinal, or hilar lymph nodes or tonsils. If the blood and marrow (when indicated, as discussed in the previous sections) fail to provide a diagnosis, biopsy of enlarged lymphoid tissue should be considered. The presence of a variety of signs and symptoms may modify and shortcut the diagnostic evaluation.

How large must lymphoid tissue be before it is considered abnormal? Exact limits cannot be set. The answer varies with the age of the patient, his occupation, and the location of the lymph nodes. Careful physical examination by an experienced physician reveals palpable small lymph nodes and visible tonsillar tissue in almost all patients.

The most common cause of lymphoid enlargement is cellular proliferation (antibody production) in response to antigenic stimulation. The frequency of trychophyton infection of toes and trauma to feet and legs is reflected in the frequency of palpable inguinal nodes (usually less than 1 cm in diameter in most patients). If the patient's occupation or

hobby leads to frequent trauma of hands and arms, then small palpable epitrochlear and axillary nodes are expected. Thus, the assessment of the lymphoid system in a laborer differs somewhat from that of an educator (unless the latter's hobby is gardening and hunting).

Children and adolescents commonly have more palpable nodes than do adults. This is presumed to reflect their more frequent exposure to antigens new to their experience. Thus, significant generalized adenopathy has a more liberal definition in the young than in adults. This is particularly true of tonsils. Rather prominently visible tonsils, protruding into the oropharynx, are expected in preschool children but are uncommon in adults.

Thus, clinical judgment based on experience with many patients is necessary in the diagnosis of "abnormally" enlarged lymphoid tissue. If lymphoid tissue is unequivocally enlarged, however, prompt, thorough evaluation is indicated. If doubt exists as to whether there is significant enlargement, the choice between immediate biopsy or periodic observation to discover whether the nodes will enlarge or shrink should be made on the basis of ancillary findings. If there are other signs and/or symptoms suggesting a lymphoma, biopsy of small, questionably enlarged nodes may yield a diagnosis. If it is decided to delay biopsy, then periodic observation should not be allowed to lead to procrastination. Biopsy should be performed after no more than one or two months of observation if the physician is still suspicious that the nodes are abnormal.

The causes of enlargement of lymph nodes are extremely varied. In Table 40-1, the major categories of disease leading to lymphadenopathy are presented. This table is in no sense exhaustive.

Certain physical characteristics of nodes aid in the diagnosis of the cause of lymphadenopathy. Infected nodes usually are tender and the overlying skin often is inflamed. Such nodes may be matted together. In certain types of infection, such as tuberculosis, aspergillosis, or actinomycosis, sinus tract formation is common. Infected nodes may be

Table 40-1. Conditions Leading to Lymph Node Enlargement

---

I	Lymphadenopathy due primarily to immune response
A	Infections
1	Pyogenic infections
a	Local enlargement of nodes draining areas of local infection (eg furuncles caused by staphylococci, oral infection)
b	Generalized enlargement from fairly indolent infections (eg <i>Salmonella</i> septicemia, bacterial endocarditis)
2	Viral infections
a	Local enlargement of nodes draining portals of entry of infection (eg cat scratch fever, lymphogranuloma venereum)
b	Generalized lymphadenopathy with systemic infections (eg infectious mononucleosis, measles, infectious hepatitis)
3	Miscellaneous types of organisms
a	Local enlargement of nodes draining the portal of entry of such infections as cryptococcosis, primary chancre of syphilis
b	Generalized adenopathy (eg secondary syphilis, toxoplasmosis)
B	Lymphadenopathy secondary to an immune response to noninfectious agents (eg, serum sickness following injection of foreign protein)
II	Lymphadenopathy due primarily to infection of the node by organisms
A	Pyogenic infection, the classic example is the bubo of <i>Pasteurella pestis</i> , more commonly abscess formation by staphylococcal invasion
B	Granuloma formation. The entrance of tubercle bacilli or fungi such as <i>Histoplasma capsulatum</i> into nodes often results in granuloma formation as well as hypertrophy, identifiable organisms are present within the granuloma in many instances
III	Neoplastic evolution or invasion of nodes
A	Primary neoplastic diseases of nodes
1	Hodgkin's disease and non-Hodgkin's lymphomas (NHL) (Chapters 50 and 51)
2	Lymphoid leukemia: chronic lymphocytic leukemia, acute lymphoblastic leukemia (Chapters 47 and 49)
3	Other neoplastic disease of nodes such as lymphoepithelioma
B	Secondary neoplastic processes occurring in nodes
1	Myeloid leukemias, acute myeloblastic leukemia, chronic myelocytic leukemia (Chapters 47 and 48)
2	Idiopathic myelofibrosis with extramedullary hematopoiesis producing lymph node enlargement (Chapter 57)
3	Metastases from carcinoma producing lymph node enlargement
IV	Diseases of unknown cause leading to lymph node enlargement (usually generalized)
A	Autoimmune diseases (diseases which perhaps result from immunologic recognition of the patient's tissue as foreign tissue)
1	Systemic lupus erythematosus, rheumatoid arthritis, and other "collagen vascular" diseases
B	Reaction to drugs
1	Hydantoins and related chemicals
C	Miscellaneous diseases
1	Granuloma formation as seen with sarcoid or in patients exposed to beryllium
2	Reactive hyperplasia as seen in hyperthyroidism

---

fluctuant. Nodes undergoing an immune response to infection also may be tender, but other signs of inflammation usually are absent. Tenderness may be due to other conditions but this is uncommon. Carcinomatous nodes usually are very hard, may be bound to one another and to surrounding tissues; lymphomatous nodes are more often firm, rubbery, discrete, and freely movable.

The location of the nodes may be helpful.

Large, bilateral hilar nodes without other detectable adenopathy are unusual in patients with lymphomas and are more suggestive of sarcoidosis.

Careful questioning of the patient is necessary since trauma or infection distal to the local enlargement may have been forgotten or the patient may fail to mention recent systemic symptoms which could account for generalized enlargement. It is known that

animals, given antigen subcutaneously, produce most of the specific antibody in nodes draining the injection site; intravenous antigen results in widespread antibody production, particularly in the spleen.<sup>26</sup> Considering the variety of diseases associated with lymphadenopathy (Table 40-1) it is apparent that many systems of the body must be assessed and any symptoms, signs, or laboratory abnormalities carefully evaluated. Cervical node metastases from a nasopharyngeal tumor may overshadow the primary tumor which is often small and easily overlooked unless a careful nasopharyngeal examination is made.<sup>21</sup> Relatively asymptomatic infection with parasites of the genus *Toxoplasma* is quite common in many parts of the world and may produce lymphadenopathy.<sup>18</sup> Determination of dye titers to the organism is thus a useful screening procedure for patients with unexplained adenopathy and if the toxoplasmosis is active a rising titer should be found. If evaluation discloses or suggests a self-limited process which reasonably explains enlarged lymph nodes, observation rather than immediate biopsy is justified.

As noted in the preceding sections, in certain situations, as when leukemia or multiple myeloma is suspected, bone marrow biopsy in addition to careful examination of the blood can be justified before performing a lymph node biopsy. Sometimes needle biopsy of the liver may be considered preceding lymph node biopsy, especially if the liver is enlarged.

In general, excisional biopsy is the procedure of choice. However, if there is a strong presumption of metastatic carcinoma or direct infection of the node, needle biopsy or aspiration<sup>2,9</sup> may be considered. The procedure for *lymph node puncture* is simple. The overlying skin is cleansed and sterilized. No anesthesia is necessary. Using a 20-gauge sterile needle and dry syringe the operator grasps the node securely between thumb and index finger and pierces the node. The tissue is aspirated rapidly and the needle is then withdrawn. Smears of the aspirate are made on a clean slide and stained with Wright's stain. Bacterial culture and staining by

Gram's method should also be carried out. A diagnosis of Hodgkin's disease, non-Hodgkin's lymphoma, lymphadenitis, or other conditions causing lymph node enlargement (Table 40-1) may be established by lymph node puncture.<sup>2,9,34</sup> However, excisional biopsy yields much more tissue for diagnostic studies, facilitating multiple histologic section preparation for routine and special stains as well as providing more adequate material for culture. Smears from lymph node puncture allow more exact definition of individual cells than do sections from biopsy, but if imprints are made from the biopsy material this advantage is negated. Histologic diagnosis depends upon changes in the overall architectural pattern of the lymph node as well as upon identification of individual cells, and sections from excisional biopsy specimens are superior to material obtained by needle biopsy of lymph nodes for histologic study. As a consequence, lymph node puncture should be restricted to the very rare patient who refuses to allow performance of excisional biopsy but will allow lymph node puncture.

For excisional biopsy, preference is given to the largest palpable node available. More than one node should be removed, if possible, and irradiated areas should be avoided. As a general rule, biopsy of cervical or supraclavicular nodes is preferable to biopsy of axillary nodes and any of these is preferable to biopsy of inguinal nodes when other considerations are equal. As previously mentioned, inguinal nodes are frequently enlarged from chronic foot infection and when this is the case the architecture often is distorted. Axillary nodes, unless markedly enlarged, may be difficult to find during surgical procedures because of the complex and changed anatomy during exposure of this area. All biopsied nodes should be cultured for various organisms as well as examined in stained sections.

*Imprint preparations* of biopsied lymph nodes also are helpful in the detailed morphologic study of cells. Imprints are made by gently pressing the cut surface of the node on a clean glass slide. This should be done repeatedly as the initial imprint may yield too

thick a cellular layer for accurate morphologic study of individual cells. The slides are stained with Wright or Giemsa stains as for the study of blood smears (Chapter 1).

A mediastinal mass without other physical evidence of disease is found in a few patients with Hodgkin's disease or non-Hodgkin's lymphoma (NHL). Mediastinoscopy may yield a correct diagnosis, allowing one to avoid the more major procedure of thoracotomy.

The results of histologic examination of lymph node biopsy specimens are generally divisible into the following five categories:

1. Hodgkin's disease or NHL. Unless the patient has received medication such as the hydantoin which can produce "lymphomatous" changes that may be reversible when medication is discontinued (Chapter 50),<sup>15,20</sup> the diagnosis is established.

2. Specific infections such as tuberculosis or histoplasmosis

3. Carcinoma.

4. Granulomatous changes without demonstrable infecting organisms. If caseation is present, it is assumed that the lymphadenopathy is a tuberculous or other infectious process; routine culture may disclose tuberculosis or fungal infections. Noncaseous granulomas are encountered in nodes removed from patients with a wide variety of diseases such as sarcoid, beryllium intoxication, Hodgkin's disease, Rocky Mountain spotted fever, and Q fever.

5. "Reactive hyperplasia" or nodes which are normal in pathologic appearance

A histologic appearance of reactive hyperplasia or of nonspecific granulomatous changes does not rule out the possibility of Hodgkin's disease or NHL. Since enlarged nodes from patients known to have Hodgkin's disease may not show evidence of the disease,<sup>16</sup> it is not surprising that the first biopsy may give negative findings in a patient in whom a second biopsy gives positive indication of the condition (Chapter 50). In lymphocytic lymphoma, as discussed in Chapter 51, the infiltration may be very orderly and the lack of distortion of normal nodal architecture leaves one hesitant to make this diagnosis. If more than one node is removed

initially, the likelihood of positive findings is enhanced. In nondiagnostic biopsies the decision to obtain more tissue for further study must be individualized. If there are no other enlarged nodes and there are few or no symptoms, observation may be advisable. Prompt diagnosis and proper therapy are quite important in bacterial and fungal infections and perhaps in Hodgkin's disease (Chapter 50), but are less important for the eventual outcome of the other conditions listed in Table 40-1.

## Examination of The Spleen

Many of the conditions leading to lymphadenopathy (Table 40-1) also produce a palpably enlarged spleen. Consequently, the preceding discussion regarding evaluation of the patient with lymphadenopathy is equally applicable to the patient with splenomegaly. When splenomegaly is associated with systemic infection (acute splenic tumor), the spleen usually is barely palpable, soft to firm, but not hard, and splenomegaly disappears shortly after recovery from the infection. A palpable spleen usually indicates disease, but we agree that a soft spleen tip can be palpated in approximately 1 to 2% of apparently healthy persons.<sup>23</sup> The differential diagnosis of splenomegaly is discussed in detail in Chapter 45.

Splenic puncture (Chapter 45) may be helpful in certain conditions (eg, leishmaniasis, kala-azar<sup>24,33</sup>). As compared to aspiration, needle biopsy increases the chance of a correct diagnosis being reached, but biopsy carries a greater risk than does aspiration.<sup>4</sup> Diagnostic splenectomy is required in some patients, especially those in whom the only palpably enlarged tissue is the spleen. However, before a diagnostic splenectomy is considered, numerous other studies should be made; in most cases these will indicate the diagnosis. For instance, splenic hypertrophy due to increased red cell destruction, such as in hereditary spherocytosis (Chapter 21) and thalassemia (Chapter 26), or that associated with increased platelet destruction, as in idiopathic thrombocytopenic purpura (Chapter 34), should be detected by means of appro-

priate blood and other examinations. Biopsy of enlarged nodes should always be carried out before splenectomy is considered. Liver function tests and needle biopsy of the liver should be done to exclude, among other considerations, the possibility that the splenomegaly is due to hepatic disease producing increased portal pressure. Congestive splenomegaly caused by extrahepatic vascular obstruction can often be detected by a percutaneous splenoportogram. However, if such is the case, an abdominal operation is indicated and the added hazard of the splenoportogram may not be justified.

Indications for splenectomy are discussed in Chapter 45 and elsewhere, in relation to the various diseases associated with splenomegaly.

## Fever of Unknown Origin (FUO)

On occasion, the presenting manifestation of patients with Hodgkin's disease and, more rarely, those with non-Hodgkin's lymphoma may be fever, often accompanied by weight loss and occasionally by generalized pruritus, but without palpably enlarged lymphoid tissue, no mediastinal disease evidenced by chest x ray, and with normal or nondiagnostic blood or bone marrow. In contrast, when fever is the presenting manifestation of acute leukemia, examination of the blood or at least of the bone marrow, should reveal the diagnosis. Thus, the lymphomas must be considered in the workup of a patient with FUO.

In such a patient it may be wise to do a needle biopsy of the liver whether or not hepatomegaly is present. Such a procedure rarely yields a diagnosis of lymphoma unless the liver is enlarged but the possibility of other fever-producing diseases such as visceral or miliary tuberculosis may be ruled out. For the same reason, bone marrow biopsy and culture should be performed.

Fever due to lymphoma with no palpable disease is usually associated with retroperitoneal lymph node enlargement. The most reliable nonsurgical technique for evaluating retroperitoneal lymph nodes is lymphangiography (Chapter 50). However, certain abdominal nodes such as the pararectal, perivesical, omental, and those of the hilus of the spleen and liver are not made visible by radiopaque dye introduced into lymphatics of the feet.<sup>16</sup> If the lymphangiogram discloses enlarged nodes, exploratory laparotomy with node biopsy, open liver biopsy, and perhaps splenectomy are in order. If the lymphangiogram demonstrates no abnormality, exploratory laparotomy may still occasionally reveal lymphoma. In general, if there are no signs, symptoms, or laboratory or radiologic findings suggesting intra-abdominal disease, diagnosis of FUO by exploratory laparotomy is successful in only a very small percentage of patients.<sup>3</sup>

## Recurrent Infections

Although severe infection may develop for no apparent reason in otherwise healthy individuals, recurrent infection should raise the suspicion of defects in cellular or humoral defense mechanisms.

The blood of any patient with infection should be examined carefully. In the presence of pyogenic bacterial infection severe enough to produce fever, neutrophilia is anticipated. If neutrophilia is absent, or indeed if the patient is neutropenic (less than  $1.8 \times 10^9$  neutrophils/l), a neutrophil deficit should be suspected as the cause of the infection (Chapter 42). It must be remembered, however, that overwhelming infections such as pneumococcal pneumonia involving multiple lobes of the lung may produce neutropenia in the absence of leukocytic disease through increased neutrophil utilization in the infection<sup>22</sup> (Chapter 41). In addition, neutrophilia is commonly absent in certain bacterial infections such as brucellosis and typhoid fever.<sup>27</sup> However, in most instances of pyogenic bacterial infections, neutropenia is indicative of overwhelming sepsis or of an underlying factor in the development of the infection.

In repeated infections, evaluation of the immune system and the functional capacity of the neutrophils is in order even if the quantitative neutrophil response to infection is appropriate. Immunologic deficiency is a

more common cause of increased susceptibility to infection than are functional defects of the neutrophil response. Hypogammaglobulinemia is usually accompanied by pyogenic bacterial infection, whereas defects in cellular immunity lead to viral infections such as herpes zoster, or fungal infections such as candidiasis or tuberculosis. Nevertheless, while the type of recurrent infection often points towards a particular defect, both the antibody-producing system and the cellular immune system should be investigated in all instances.

The investigation of the immune system has been discussed in detail in Chapter 7. Immunoglobulin levels may be assessed qualitatively by means of paper electrophoresis or immunoelectrophoresis, and can be measured quantitatively by a variety of techniques. Secretory immunoglobulins should also be examined. In addition, it is frequently useful to evaluate an individual's ability to produce antibodies towards specific bacterial and other antigens.

If reduced immunoglobulins are found, various primary and secondary immune deficiencies need to be considered. These are discussed in detail in Chapter 44. Causes of secondary hypogammaglobulinemia include chronic lymphocytic leukemia<sup>32</sup> (Chapter 49) which is easily diagnosed by its characteristic clinical and hematologic findings, and non-Hodgkin's lymphoma, which often requires a more diligent search (Chapter 51). The serum, urine, and bone marrow should be examined for evidence of one of the plasma cell dyscrasias (Chapters 52 and 53). Examination of the bone marrow is also useful in the investigation of primary defects in antibody production, since plasma cells are absent in many of them (Chapter 44).<sup>15</sup> When reduced immunoglobulins are due to renal protein loss, the nephrotic syndrome is usually present and is readily recognized. Protein-losing enteropathy also may lead to hypogammaglobulinemia, and sometimes gastrointestinal symptoms may be minimal.<sup>14</sup>

Defective cellular immunity may be accompanied by lymphopenia, as in severe

combined immune deficiency<sup>10,31</sup> or Hodgkin's disease<sup>1,30</sup> but the causes of lymphopenia are so varied (Chapter 41) that it is an unreliable index of defective cellular immunity. Reliable methods of assessing cellular immunity include: (1) the subcutaneous injection of antigen, which yields delayed hypersensitivity responses in the presence of immunity, (2) testing sensitization to contact allergens such as dinitrochlorobenzene (DNCB), and (3) a host of *in vitro* tests of lymphocyte function, including the response to phytohemagglutinin and specific antigens.<sup>19</sup> All of these tests and others have been discussed in detail in Chapter 7. The diseases causing secondary defects in cellular immunity are usually obvious; they include Hodgkin's disease, sarcoidosis, and certain advanced malignant lesions (Chapter 44).

If at this point in the patient's workup, no explanation for recurrent or persistent infections has been discovered, the possibility of a functional defect in the neutrophil system should be considered. Four classes of defects in neutrophil participation in inflammatory exudates have been described<sup>11</sup>: (1) intrinsic, but undefined, neutrophil defects resulting in markedly reduced ability of the cell to migrate from the blood to exudates; (2) normal neutrophils but defective chemotactic factors so that neutrophils are not attracted to exudates (Chapter 41); (3) defective killing of phagocytized organisms due to lysosomal enzyme deficiency; and (4) defective killing of phagocytized organisms due to as yet incompletely defined metabolic defects in the neutrophil. Neutrophil defects may be inherited or acquired, either as idiopathic syndromes or secondary to various diseases<sup>11</sup> (Chapter 42). Since all of these are newly defined classes of defects, their frequency is unknown. In order to test for their presence one must assess neutrophil migration into induced exudates<sup>7</sup> and test the ability of neutrophils to kill phagocytized organisms.<sup>11</sup> Since killing defects are sometimes limited to specific bacteria<sup>17</sup> the ability of the patient's neutrophils to kill his infecting organisms should be studied.

Finally, it is necessary to stop when a diag-

nosis has been made. For example, in a 60 year old man with symptoms limited to fatigue, physical examination which discloses generalized adenopathy and blood containing  $30.0 \times 10^9$  or more small lymphocytes/l, the diagnosis of chronic lymphocytic leukemia is established and bone marrow examination and lymph node biopsy provide no further diagnostic information. Too often, one sees patients in whom unnecessary biopsy procedures have been carried out.

ognized as measures of the reaction of the body to disease processes and noxious agents. In many instances these alterations give useful indications of the nature of the pathologic process, and they may be seen not only in acute infections but also in many chronic ailments as well.<sup>65 69,73</sup>

## **Leukocytes in Inflammation**

It was emphasized in Chapters 6 and 7 that the major leukocyte functions are accomplished in the tissues and that the leukocytes in the blood, even in normal persons, are in transit from sites of production or storage to the tissues. From this it is evident that variations in the blood concentration of each leukocyte type can result from changes in: (1) the flow of cells into the blood, (2) the egress of cells from the blood, (3) the distribution of cells within the vascular system, or (4) combinations thereof.<sup>30,10</sup> Furthermore, these changes may be of brief duration, and thus easily missed, or they may persist for days or weeks. Quantitative measurement of such changes in distribution and in inflow and egress rates has been possible only in recent years, and for only one or two of the leukocyte types (pages 249, 269). However, these studies have provided some insight concerning the pathophysiologic significance of the leukocyte variations seen in disease states.

Also helpful in gaining an understanding of the leukocyte responses noted in disease

Alterations in the blood leukocyte concentration and in the relative proportions of the several leukocyte types have long been rec-

have been a variety of *experimental models of inflammation*. These have included observations of cell migration into sites of implanted foreign bodies as carried out by Metchnikoff and of cell migration into rabbit ear chambers<sup>8</sup> and skin windows<sup>2,15,16,175</sup>; studies of peritoneal exudates,<sup>11</sup> hypersensitivity reactions,<sup>5,6</sup> and infections<sup>50</sup> and parasitic infestations<sup>252,253,261</sup> produced in animals; and investigation of the kinetics of labeled cells in human subjects given injections of endotoxin.<sup>33,55</sup> These observations and studies have been described in extensive reviews.<sup>5,6,7,10,18,20,21</sup> It has been shown that at sites of tissue damage, whether induced by a bacterial infection, the deposition of antigen antibody complexes, physical damage to cells (heat, freezing, irradiation, or chemicals), lysis of leukocytes as a result of their inability to digest urate crystals, or by some other means, a series of reactions referred to as the inflammatory process ensues. Although similar, these reactions are not identical in all instances and vary with the intensity, duration, extent, and type of injury.<sup>10,24</sup> In mild injuries there is an initial, transient vasodilatation of postcapillary venules accompanied by increased vascular permeability; this lasts less than 10 minutes and is thought to result from the local release of histamine.<sup>7,10</sup> There is increased blood flow to the area and a second wave of increased vascular permeability occurs during the 2- to 10-hour period following injury. This stage is accompanied by adherence of leukocytes to the vascular walls, most marked on the side nearest the injury,<sup>10</sup> and is mediated at least in part by kinins.<sup>7</sup> Diapedesis of white cells through the walls follows, neutrophils usually arriving first, with monocytes, eosinophils, basophils, and lymphocytes appearing later<sup>12</sup> in numbers that seem to be influenced by the nature of the injury.

In association with *small insults*, little change in the concentration of blood leukocytes occurs. However, if the lesion is extensive, large numbers of cells may be needed and are recruited from their sites of production or storage to enter the blood and thence to be transported to the tissues. In most bac-

terial infections, neutrophils ingest and usually kill the offending organisms, dying themselves soon thereafter. They usually are recruited in large numbers early in such infections. Macrophages ingest and remove damaged tissue cells, red cells, and neutrophils and, in general, appear to clean up the area of injury; they may even trigger the process of fibrosis and repair.<sup>1</sup> Macrophages do not usually die in performing these functions and, in fact, may be stimulated to divide at the site of inflammation, thus forming new cells.<sup>17,18</sup> Perhaps because of these properties, monocytes from which the macrophages arise appear to be recruited later than neutrophils and in smaller numbers. In some situations the neutrophils are unable to kill and digest certain foreign agents, eg, brucella, mycobacteria, toxoplasma, fungi. In these circumstances the macrophages become heavily involved in the phagocytosis and killing of the organisms and more than usual numbers are recruited for body defense. In most inflammatory lesions a few eosinophils and basophils are seen; in certain instances they are the prominent cell forms (see below). Lymphocytes appear late and in chronic lesions. In infections or trauma the inflammatory processes seem purposeful and result in protection of the organism. However, in other situations this is not always the case. For example, the ingestion of urate<sup>21</sup> or silica particles<sup>1</sup> by phagocytes results in phagosome lysis, death of the cell, and release of hydrolytic enzymes into the tissues. The release of enzymes also may occur in immune reactions of several types.<sup>5,6,21,22</sup> In these situations the activities of the leukocytes are harmful to the host and produce or exaggerate disease processes; in some of these, the suppression of leukocyte numbers and activities constitutes an effective form of therapy.<sup>5,13,21</sup> In any case the inflammatory reactions that take place in the tissues may produce changes in blood leukocyte content that are useful indicators of the nature of the disease and the host's response to it.

*Leukocytosis* refers to an increase above normal in the total number of leukocytes; that is, an increase above  $10.0 \times 10^9$  cells/l

(Table 6-4, page 242). In certain pathologic conditions, leukocyte counts of  $15.0$  to  $25.0 \times 10^9/l$  are common and values as high as  $40.0 \times 10^9$  cells/l are not unusual. Occasionally higher counts, even as high as  $100 \times 10^9$  cells/l may be found (see Leukemoid Blood Pictures, page 1301). Most commonly, leukocytosis is due to an increase in the number of neutrophils, and thus the term is often, but incorrectly, considered synonymous with *neutrophilia*. Less often leukocytosis may be due to an increase in lymphocytes (see page 1288). Leukocytosis due to eosinophilia, monocytosis, or basophilia is relatively rare.

*Leukopenia* refers to a decrease in the total leukocyte count below  $4.3 \times 10^9$  cells/l. Usually the reduction is due to a decrease in the number of neutrophils (*neutropenia*); however, when leukopenia is marked, lymphocytes and other cell types also are affected.

It must be appreciated that the concentration of several of the leukocyte types may change at the same time and in the same or in opposite directions. For example, in many acute infections the blood neutrophil concentration increases while there is a simultaneous decrease in lymphocytes and eosinophils. Significant changes in the less numerous cell forms, the eosinophils, basophils, and monocytes, may occur in the absence of changes in the total cell count. For these reasons and because it is now evident that each cell system has its own unique functions and control mechanisms it is best to determine the "absolute" blood concentration of each cell type (page 237). By this means, changes in the concentration of eosinophils, basophils, or monocytes will be detected as well as the more obvious changes in neutrophils and lymphocytes. Such information can provide significant clues to the alert physician.

## The Neutrophil Series

### Causes of Neutrophilia (Table 41-1)

ACUTE INFECTIONS. Neutrophilia may be due to acute infections, especially those caused by *cocci* (staphylococcus, strepto-

Table 41-1. Causes of Neutrophilia

- 1 *Acute infections*, local or generalized especially *coccal* but also those due to certain bacilli, fungi, spirochetes, parasites, and some viruses in diseases usually not associated with neutrophilia when complications develop
- 2 *Other inflammation* tissue damage resulting from burns or following operations, ischemic necrosis as in myocardial infarction, gout collagen vascular disease, hypersensitivity reactions, and other similar inflammatory processes
- 3 *Intoxication*
  - a Metabolic, including uremia diabetic acidosis, eclampsia
  - b Poisoning by chemicals and drugs lead, digitalis, insect venoms, foreign protein
- 4 *Acute hemorrhage*, internal, external
- 5 *Acute hemolysis*
- 6 *Malignant neoplasms*
- 7 *Physiologic neutrophilia* during strenuous exercise, after epinephrine injection, in association with convulsions or paroxysmal tachycardia and in the newborn
- 8 *Myelocytic leukemia*, polycythemia vera, myelofibrosis and myeloid metaplasia
- 9 *Other causes* chronic idiopathic neutrophilia, adrenocorticosteroids

coccus, pneumococcus, gonococcus, meningococcus) and by some bacilli (*E. coli*, *Pr. aeruginosa*, *C. diphtheriae*, *P. tularensis*), as well as certain fungi (*Actinomyces*), spirochetes (*L. icterohemorrhagica*), viruses (rabies, poliomyelitis, herpes zoster, smallpox, chickenpox), *rickettsia* (typhus) and *parasites* (liver fluke, coccidiosis immitis). It is found in association with *localized infections* such as furuncles, carbuncles, abscesses, tonsillitis, otitis media, and osteomyelitis, but often is most prominent in more *widespread infections* such as pneumonia, cholecystitis, salpingitis, meningitis, diphtheria, anthrax, plague, peritonitis, and appendicitis, to cite just a few.

In acute infections, leukocyte counts of  $15.0$  to  $25.0 \times 10^9$  cells/l are usually found. In pneumococcal pneumonia, higher counts ( $20.0$  to  $40.0 \times 10^9/l$ ) are characteristic and to some degree reflect the extent of the process; in bronchopneumonia a moderate leukocytosis is common.

The absence of leukocytosis is very helpful in differentiating typhoid fever, paratyphoid

fever and glands from pyogenic infections; leukocytosis also is usually absent in uncomplicated mumps, measles, and many viral infections. In these infections the presence of neutrophilia has been regarded as indicating the onset of complications, such as meningitis or orchitis in mumps, bowel perforation in typhoid fever, or bacterial infection in measles.<sup>65</sup> Nevertheless, leukocytosis has been observed in viral disease of the respiratory tract apparently in the absence of complicating infections<sup>68</sup> and is common in smallpox and chickenpox. In tuberculosis, neutrophilia is usually minimal or absent except in association with acute local spread, as in tuberculous meningitis or following rupture of caseous foci into the pleural space or into a bronchus.

**OTHER INFLAMMATION.** Leukocyte counts as high as  $73 \times 10^9$  cells/l have been reported in patients with severe burns; this is accompanied by a shift to the left and the presence of "degenerative" forms<sup>71</sup> including "toxic" granulation and Dohle bodies (page 1278). *Postoperatively*, neutrophilia occurs for 12 to 36 hours, perhaps as the result of the extensive tissue injury. In *coronary thrombosis*, neutrophilia regularly occurs and is valuable in distinguishing this condition from angina pectoris and more prolonged episodes of pain ("coronary insufficiency") that are not accompanied by tissue necrosis. Leukocytosis also occurs in intestinal obstruction and strangulated hernia, but many insist that it does not occur until peritonitis has set in. Neutrophilia commonly occurs during acute attacks of gout and may reach values of  $30.0 \times 10^9$ /l; this inflammatory reaction appears to result from the binding of uric acid crystals to phagosome walls, the rupture thereof, and finally the release of hydrolytic enzymes into the cell and then into the surrounding tissues.<sup>21</sup>

Neutrophilia occurs in acute glomerulonephritis, serum sickness, and rheumatic fever and in a number of the *collagen vascular diseases* that are thought to represent immune reactions. The appearance of neutrophils in certain types of hypersensitivity lesions (eg,

Schwartzman and Arthus reactions and experimental nephritis) suggests that a similar mechanism may be involved in these conditions.<sup>5,6</sup> This is yet to be proved. Of all the exanthems, leukocytosis is most marked in scarlet fever where counts as high as  $40.0 \times 10^9$ /l may be observed.

**INTOXICATIONS.** Intoxications include metabolic disorders and poisoning.

**METABOLIC DISORDERS.** In *ketoacidosis*, infections and other inflammatory lesions which may have precipitated the ketotic state should not be overlooked. Neutrophilia is especially prominent in the *uremic* patient with pericarditis or other inflammation related to the severe azotemia. The neutrophilic increase in *eclampsia* is poorly understood, but may in part reflect inflammation and in part may be caused by the convulsions.

**POISONING.** Poisoning by a variety of chemicals and drugs—lead, mercury, illuminating gas, potassium chlorate, digitalis, camphor, antipyrine, acetanilid, phenacetin, pyridine, pyrogallol, turpentine, benzene derivatives, arsphenamine—as well as by insect venoms, such as the venom of the black widow spider, may result in leukocytosis and neutrophilia. The response is almost certainly related to the degree of tissue necrosis produced and whether or not vomiting, convulsions, or a hypersensitivity reaction develops. A number of the above-mentioned drugs have also been found to cause a reduction in the leukocyte count, especially in the number of neutrophils. This effect may depend on the degree and nature of the poisoning, leukocytosis occurring when the effect is temporary or less serious. In *lead colic*, counts as high as  $20.0 \times 10^9$  leukocytes/l may be found; muscular activity may account for the leukocytosis in this situation and in delirium tremens. The injection of *foreign protein*, such as typhoid vaccine or endotoxin, produces a transient decrease in leukocyte count which occurs one and two hours after injection followed by an increase in leukocyte count (Fig. 41-5). Similar reactions are noted in serum disease and during the Jarisch-Herxheimer reaction.<sup>66,70</sup>

**ACUTE HEMORRHAGE.** Leukocytosis develops within an hour or two following the onset of acute hemorrhage.<sup>67</sup> It is greater when the bleeding occurs into the peritoneal cavity, the pleural space, a joint cavity, or adjacent to the dura than when the bleeding is external. In ruptured tubal pregnancy the count may be as high as  $22.0 \times 10^9$  cells/l. When the skull is fractured and there is associated intracranial bleeding or in subarachnoid hemorrhage, even higher counts are sometimes found. A value as high as  $31.0 \times 10^9/l$  has been observed following rupture of the spleen. The mechanism by which leukocytosis and neutrophilia develop in such cases is poorly understood. Since small volumes of blood may cause marked neutrophilia in some instances, pain with release of adrenal corticosteroids and/or epinephrine may be involved. In addition, local inflammation, perhaps due to pressure necrosis and/or the lysis of leukocytes with release of hydrolytic enzymes, may also contribute, possibly by generating chemotactic factors (page 257). Large external hemorrhages also cause neutrophilia, but in these the rate and amount of blood lost seem to be important factors<sup>67</sup>; the lack of eosinopenia in phlebotomized dogs militates against an adrenocorticoid mediated mechanism.<sup>67</sup>

**ACUTE HEMOLYSIS.** In mismatched transfusions, inadvertent infusion of hypotonic solutions, or acute hemolytic diseases, marked leukocytosis may occur.

**MALIGNANT NEOPLASMS.** Rapidly growing neoplasms may cause neutrophilia, presumably as a result of necrosis within areas that have outgrown their blood supply. When the liver, gastrointestinal tract, or bone marrow are involved, the counts may be especially high (see Leukemoid Blood Pictures). There is also evidence in animals that some tumors may contain hormone-like substances that cause leukocytosis (page 1303).

**PHYSIOLOGIC NEUTROPHILIA.** Transient neutrophilia occurs in association with vigorous exercise or after the injection of epinephrine<sup>33</sup> (page 249). Similarly, neutrophilia

occurs in association with convulsions and in paroxysmal tachycardia and during labor. It is also seen in the newborn.

**CHRONIC MYELOCYTIC LEUKEMIA AND POLYCYTHEMIA VERA.** In chronic myelocytic leukemia neutrophilia is associated with a marked "shift to the left" with metamyelocytes, myelocytes, and even younger forms in the blood, while in polycythemia vera there is usually little or no shift to the left. A few leukemia patients have been observed in whom the predominating cells in the blood were polymorphonuclear neutrophils (see Chapter 48).

**OTHER CAUSES.** Rarely, neutrophilia, with total leukocyte counts as high as  $43.0 \times 10^9$  cells/l, has been observed in the absence of any of the above disorders, and has persisted for a long time without a cause being discovered.<sup>72</sup>

The production of neutrophilia by the acute or chronic administration of adrenocorticosteroids is well recognized.<sup>33,37</sup> Neutrophilia is commonly seen in Cushing's disease.

### Causes of Neutropenia (Table 41-2)

**ACUTE INFECTIONS. BACTERIAL INFECTIONS.** Typhoid and paratyphoid fever and sometimes tularemia are commonly mentioned as acute infections accompanied by leukopenia. In typhoid fever, considerable variation in total leukocyte count occurs, with values ranging from  $1.9$  to  $25.0 \times 10^9$  cells/l.<sup>102</sup> A total leukocyte count greater than  $10.0 \times 10^9$  cells/l was reported in only 9% of 189 typhoid fever patients, while neutropenia was present in 47%.<sup>115</sup> Early in the disease (first week), mild leukocytosis and neutrophilia may be present,<sup>102</sup> but polymorphonuclear numbers then decrease to a minimum when bacteremia appears.<sup>81,102</sup> Minimum neutrophil concentrations seldom fall below  $0.6 \times 10^9$  cells/l,<sup>106</sup> but agranulocytosis has been reported.<sup>81</sup> The paratyphoid fevers (salmonellosis) produce a similar clinical picture.<sup>115,119</sup> In tularemia of the typhoidal or pulmonary type, absence of leukocytosis also

is the rule.<sup>80,82,138</sup> In a series of 225 patients with varying types of tularemia the average leukocyte concentration was 11.2 (range 2.0 to  $90.0 \times 10^9$  cells/l), but in only five patients was the leukocyte count less than  $5.0 \times 10^9$  cells/l.<sup>132</sup> In a series of 888 patients with *brucellosis*, most of whom had the severe and acute form of the disease, leukocyte counts less than  $4.5 \times 10^9$  cells/l were noted in 144<sup>93</sup>; even in those patients with leukopenia, neutropenia was minimal.

**VIRAL INFECTIONS.** A wide variety of viral diseases produce leukopenia and neutropenia. The best documented are yellow fever (acquired accidentally in the laboratory<sup>86</sup>), experimentally induced sandfly fever,<sup>137</sup> and infectious hepatitis.<sup>111</sup> In these diseases a gradual fall in leukocyte count begins usually during the second day of fever and reaches a nadir between the fourth and sixth days (Figs. 41-1 and 41-2); this fall reflects a decrease in both neutrophils and lymphocytes, neutropenia being more prominent in some viral infections and lymphopenia in others; counts may or may not reach levels of absolute neutropenia or absolute lymphopenia. In sandfly fever (Fig. 41-1), over 90% of patients develop leukopenia, and an absolute neutropenia with an increase in immature neutrophils is said to be a constant finding.<sup>137</sup> In infectious hepatitis, both neutropenia and lymphopenia are common and precede the onset of icterus (Fig. 41-2); with the rise of leukocyte concentration toward normal, atypical lymphocytes appear in the blood.<sup>111,123a</sup> In yellow fever, leukopenia of 1.5 to  $2.5 \times 10^9$  cells/l with neutropenia of 0.5 to 1.0 and also lymphopenia are common, usually occurring on about the fifth day.<sup>86</sup> Many other acute infections caused by viruses are characterized by such changes<sup>101</sup>; these include measles either naturally acquired<sup>85</sup> or occurring after inoculation with live vaccine,<sup>91</sup> chickenpox,<sup>114</sup> rubella,<sup>112,125</sup> Colorado tick fever,<sup>116</sup> dengue, and hemorrhagic fever.<sup>90</sup> Leukopenia sometimes occurs in *infectious mononucleosis*<sup>128</sup> (Chapter 43). Depletion of mature neutrophils in the marrow has been reported in *Colorado tick fever*<sup>116</sup> and

**Table 41-2. Causes of Leukopenia and/or Neutropenia**

- 1 *Certain infections*
  - a *Bacterial* typhoid, paratyphoid, less often brucellosis, rarely tularemia
  - b *Viral* eg, influenza, measles, infectious hepatitis, chickenpox, rubella, Colorado tick fever, dengue, yellow fever, sandfly fever
  - c *Rickettsia* rickettsial pox, typhus, Rocky Mountain spotted fever
  - d *Protozoal* malaria, kala azar, relapsing fever
- 2 All types of overwhelming infections eg miliary tuberculosis, septicemia, especially in debilitated patients with poor resistance
- 3 *Effect of physical agents, chemicals, and drugs*
  - a Chemical and physical agents that produce marrow hypoplasia and aplasia in all subjects if given in sufficient dose, eg, ionizing radiation, benzene, nitrogen mustards, urethane, antimetabolites (eg, folic acid antagonists, purine and pyrimidine analogues), periwinkle alkaloids (eg vincblastine) colchicine
  - b Chemicals and drugs that occasionally produce leukopenia apparently as a result of individual sensitivity eg aminopyrine, phenothiazines, sulfonamides, antithyroid drugs, anticonvulsants, antihistamines, tranquilizers, antimicrobial agents
- 4 *Certain hematologic and other conditions of unknown or poorly defined etiologic basis*
  - a Those that may be due to decreased or ineffective production, eg pernicious anemia, aplastic anemia, chronic hypochromic anemia
  - b Those that may be due to increased utilization or destruction eg cirrhosis of the liver with splenomegaly, lupus erythematosus, Felty's syndrome, Banti's syndrome, Gaucher's disease
- 5 Cachexia and debilitated states (alcoholism, etc)
- 6 In anaphylactoid shock and in early stages of reaction to foreign protein
- 7 Certain rare hereditary, congenital or familial and miscellaneous disorders (cyclic neutropenia, chronic hypoplastic neutropenia, infantile genetic agranulocytosis, primary splenic neutropenia) (see Chapter 42)

in *hemorrhagic fever*<sup>90</sup>; this suggests increased utilization or direct damage to polymorphonuclear cells as possible mechanisms of the blood neutropenia. The shift to the left often noted in the blood differential count and the presence of toxic granulation provide further support for this thesis (also see section on

Fig 41-1. The changes in the total leukocyte neutrophil, and lymphocyte concentration during experimentally induced sandfly (Phlebotomus) fever (From Sabin et al<sup>117</sup> courtesy of the authors and JAMA)

kinetics of the inflammatory reaction, page 1275)

**RICKETTSIA** Leukopenia and neutropenia may occur with variable frequency in most rickettsial infections, usually during the first week of the disease. Leukopenia is very common in *rickettsialpox*,<sup>134</sup> less so in *epidemic typhus*,<sup>144</sup> scrub typhus,<sup>103</sup> Rocky Mountain spotted fever,<sup>110</sup> and recrudescent typhus.<sup>94</sup>

**PROTOZOAL INFECTIONS** In *malaria*, slight leukocytosis ( $11.0 \times 10^9/l$ ) may be present for a short time during paroxysms, but, as parasitemia progresses, leukopenia<sup>130</sup> and shift neutropenia<sup>100</sup> develop. In relapsing fever the leukopenia is found between periods of fever; during febrile periods, the leukocyte count may be as high as  $15.0 \times 10^9$  cells/l. Leukopenia also characterizes kala-azar<sup>96</sup> and oriental sore.

**OVERWHELMING INFECTION.** Neutropenia may result from overwhelming infection of all types, eg, miliary tuberculosis<sup>84</sup> and septicemia<sup>88</sup> (Fig. 41-3). Patients with depressed marrow neutrophil reserves are particularly prone to develop neutropenia when severe infection ensues. Such patients include alcoholics,<sup>127</sup> the undernourished, and patients with primary hematologic disease or those previously treated with marrow-depressing drugs or irradiation. However, even the previously healthy may develop severe neutropenia when overwhelming infections develop<sup>88</sup> (Fig. 41-3).

**CHEMICAL AND PHYSICAL AGENTS.** Certain chemical and physical agents may produce leukopenia and granulocytopenia. These may be divided into two general categories: those causing leukopenia and neutropenia consist-

Fig 41-2 The changes in total leukocyte neutrophil and lymphocyte concentration during experimentally induced infectious hepatitis (From Havens and Marck<sup>111</sup> courtesy of the authors and the American Journal of Medical Sciences)

Fig 41-3 The blood neutrophil pattern in a previously healthy woman without other disease who developed acute pansinusitis which progressed to cavernous sinus thrombosis and terminated in streptococcal septicemia. The total neutrophil response was inadequate and the large proportion of immature forms and cells containing toxic granulations indicate an inadequate response (From Bethell,<sup>88</sup> courtesy of the author and Journal of Laboratory and Clinical Medicine)

ently and those occasionally associated with neutropenia.

**AGENTS THAT CAUSE LEUKOPENIA AND NEUTROPENIA CONSISTENTLY** If given in sufficient dose certain agents will consistently cause leukopenia and neutropenia (Table 41-2). For the most part these are agents used in the chemotherapy of malignant disease. They act mainly, if not entirely, by interfering with cell production, either by directly damaging the mitotic or stem cell compartments of the marrow (ionizing radiation, benzene) or by slowing cell division in various ways such as: (1) interfering with the purine or pyrimidine biosynthetic steps necessary for DNA synthesis (antimetabolites); (2) blocking DNA strand duplication as a result of drug binding to certain base groups in the DNA molecule (mustard analogues); (3) disrupting the microtubules of the mitotic spindle (colchicine, vinblastine, vincristine); or (4) interfering with RNA formation and the translation and transcription processes that are central to protein synthesis in all cells (certain antibiotics). Since most of these agents also suppress erythrocyte and platelet production they are discussed further in Chapters 34 and 56.

Generally, after exposure to agents of this type, the degree of neutropenia is related to dose. Also there is a variable delay before the deleterious effects on cell production are reflected in the appearance of neutropenia.<sup>93</sup> The length of the delay is related to the size of the marrow neutrophil reserve before the agent is given and the rate of consumption of cells thereafter. Thus, after complete cessation of cell production in a previously healthy person and in the absence of an increased need for neutrophils, a delay of 8 to 14 days can be expected before neutropenia will develop (page 249). On the other hand, in a chronically ill patient who may have been exposed to these agents previously, whose marrow may contain tumor, or whose reserves have been depleted for nutritional or other reasons, the interval between exposure and neutropenia may be shorter. The presence of increased neutrophil demand (infection or other inflammation) also will shorten the interval.

Unless damage to the mitotable precursors or the stem cells has been excessive, evidence of regeneration in the marrow often is apparent by the time neutropenia develops.<sup>93</sup>

**AGENTS OCCASIONALLY ASSOCIATED WITH NEUTROPENIA** (Table 41-2). These agents cause neutropenia that may be of acute onset and apparently the result of hypersensitivity (page 1292), or it may consist of a gradual reduction in cell concentration over an extended time; the mechanism of the latter process is not well understood. These neutropenias will be discussed later in this chapter (page 1292).

**HEMATOPOIETIC DISORDERS AND CERTAIN CONDITIONS OF UNKNOWN CAUSE.** Patients with chronic anemias, such as pernicious anemia, may be leukopenic and/or neutropenic, presumably because cell production is markedly impaired or "ineffective." Rarely, leukopenia or neutropenia is seen in chronic hypochromic anemia.<sup>118</sup>

Leukopenia and neutropenia also may occur in certain other conditions of poorly understood pathogenesis (Table 41-2). In patients with *cirrhosis of the liver*, especially in those with splenomegaly (page 1412),<sup>39,48,126</sup> there is a tendency to leukopenia, granulocytopenia, and monocytosis.<sup>126</sup> Leukopenia occurred in 66% of 258 patients with *lupus erythematosus*.<sup>99</sup> In *Felty's syndrome*, a condition characterized by arthritis, splenomegaly, and leukopenia, not only is there a variable reduction in concentration of neutrophils and total cell count,<sup>122,135</sup> but also increased susceptibility to infection is not uncommon (page 1408).

**CACHEXIA AND DEBILITATED STATES.** Cachexia and debilitated states associated with protein undernutrition and vitamin deficiency are accompanied by leukopenia.<sup>105</sup> Leukopenia and neutropenia are not seen in alcoholics in the absence of nutritional deficiency.<sup>120</sup>

Fig 41-4 Variations in blood neutrophil pool size and the distribution of cells in marginal and circulating sites that occur in patients with a variety of diseases. TBGP is the total granulocyte pool, CGP, circulating granulocyte pool, MGP, marginal granulocyte pool. The normal TBGP size and equal distribution of cells between MGP and CGP are illustrated in A, the continuous exchange of cells between CGP and MGP being depicted by the arrows. Alterations from normal are shown in B through I. B depicts "shift neutrophilia." C shift or "pseudo" neutropenia. D illustrates an absolute neutrophilia with increased TBGP size and equal distribution of cells in CGP and MGP. F is similar but with a greater proportional increase in MGP size. E illustrates masked granulocytosis: an increase in TBGP size without neutrophilia.

C, G, H, and I illustrate neutropenic states. C depicts shift or pseudoneutropenia, the TBGP being normal. CGP decreased. G, H, and I illustrate absolute decreases in TBGP size with different distributions of cells between marginal and circulating sites, in G the neutrophil concentration reflects the reduction in TBGP size because cells are evenly distributed in CGP and MGP. However, in H the neutropenia is more severe than the blood count indicates. In I the reverse is the case. (From Athens,<sup>31</sup> courtesy of the author and Appleton-Century Crofts.)

**ANAPHYLACTOID SHOCK.** Neutropenia is associated with anaphylactoid shock and the early stage of the reaction to parenterally introduced foreign protein or endotoxin. In sensitized animals the reinjection of the sensitizing protein results in anaphylaxis and massive accumulation of neutrophils in the lungs. During the second hour after the injection of typhoid vaccine or purified endotoxin a similar transient neutropenia develops (Fig. 41-5). The latter event apparently is due to margination of neutrophils and is soon followed by neutrophilia.

**RARE DISORDERS.** Certain additional rare disorders of which neutropenia is an important feature will be discussed in Chapter 42.

#### Neutrophil Kinetics in Patients with Neutrophilia or Neutropenia<sup>30,31,40</sup>

It has been demonstrated by means of infusions of autologous,  $DF^{32}P$ -labeled neutrophils (page 249) that an increase in blood neutrophil concentration may reflect either a shift of cells from marginal sites into the circulating granulocyte pool (CGP) without a change in total blood granulocyte pool size (TBGP) ("shift neutrophilia" [Fig. 41-4B]) or a true increase in TBGP size ("true neutrophilia" [Fig. 41-4D and F]). "Shift neutrophilia" occurs after active exercise or epinephrine injection<sup>32,33</sup>; it is of brief duration, usually lasting less than 20 to 30 minutes. It has been proposed that a similar mechanism

may explain the neutrophilia occurring after seizures or in association with paroxysmal tachycardia,<sup>32</sup> but no experimental documentation of this exists. Shift neutrophilia is usually moderate in degree ( $<15.0\text{--}20.0 \times 10^9$  neutrophils/l) and characteristically there is no increase in nonsegmented forms; that is, there is no change in inflow of neutrophils into the blood from the marrow or in egress of neutrophils from the blood.<sup>33</sup>

*True neutrophilia* is characterized by an increase in blood neutrophil concentration above  $7.25 \times 10^9$  cells/l (Table 6-4, page 242) and an increase in TBGP size above  $160 \times 10^7$  granulocytes/kg (Table 6-5, page 250). Most cases of neutrophilia due to *chronic infections* or a variety of miscellaneous diseases fall into this category (Fig. 41-4D and F). The neutrophils are predominantly mature and the TBGP size ranges from normal to five or six times normal. The distribution of cells between CGP and MGP varies considerably.<sup>35</sup>  $T_{1/2}$  values in such patients are normal or slightly prolonged and the blood granulocyte turnover rate (GTR), a measure of effective cell production, ranges from high normal values to 12 times normal.<sup>33</sup> In patients with *acute infections* the findings are similar, but it has been impossible to study patients early in infection.<sup>30</sup> From studies of two models of acute infection, namely, endotoxin injection in man<sup>31,35</sup> and bronchopneumonia produced in dogs,<sup>30</sup> it has been inferred that the changes in neutrophil kinetics can be divided into early, intermediate, and late phases. During early infection there may be a brief period during which the neutrophil concentration decreases, perhaps even to neutropenic levels, owing to margination of cells.<sup>33</sup> During this phase there is no decrease in TBGP size and, in fact, it may be somewhat increased.<sup>30,33</sup> The period of margination is rapidly followed by an influx of cells from the bone marrow into the blood<sup>30,35</sup> and an increase in TBGP size and blood neutrophilia<sup>33,30</sup>; during this early phase the  $t_{1/2}$  of labeled neutrophils is shorter than normal.<sup>50</sup> In contrast to the picture most common in chronic infections, if the demand for cells is great enough a shift to the left in the differential count occurs.<sup>50</sup> The

intermediate phase (established inflammation) is characterized by elevated neutrophil concentration in the blood and enlarged TBGP, usually with approximately equal numbers of cells in the MGP and CGP. If the infection is controlled, normal or somewhat long  $t_{1/2}$  values<sup>30,50</sup> and increased GTR<sup>35</sup> are found, but if the demand for cells is very great the marrow stores may become exhausted and neutropenia ensues.<sup>50</sup> During the late phase (recovery) there is a decreased flow of marrow neutrophils into the blood and a prolonged  $t_{1/2}$  as the neutrophilia subsides.<sup>50,55</sup>

Studies in which neutrophil precursors in the marrow were labeled with tritiated thymidine<sup>44</sup> or radiophosphate<sup>37</sup> also demonstrated more rapid release of cells to the blood in these conditions.

During the steady-state neutrophilia seen in patients with *polycythemia vera* or *myelofibrosis*, the TBGP has been found to be enlarged but an increased proportion of cells is located in the MGP (Fig. 41-4E and F) so that the neutrophil concentration does not truly reflect the increase in TBGP size.<sup>35</sup> In some patients the neutrophil concentration actually was normal although the TBGP was enlarged due to the presence of a large MGP (Fig. 41-4E). In patients with predominantly mature neutrophils in the blood the  $t_{1/2}$  values ranged from normal to 18 hours and the GTR ranged from normal to 12 times normal.<sup>35</sup> In patients with *chronic myelocytic leukemia* and in patients with myelofibrosis or myeloid metaplasia in whom increased numbers of immature neutrophils (metamyelocytes and younger forms) were present in the blood, the TBGP also was increased in size, but the  $t_{1/2}$  values were markedly prolonged (25 to 90 hours),<sup>34,46,51</sup> presumably due to the inability of immature cells to leave the blood readily<sup>39</sup> and/or because of the recirculation of immature cells to the bone marrow and spleen.<sup>54,58</sup>

An increase in TBGP size due to selective enlargement of the MGP may occur in the absence of neutrophilia and is illustrated in Figure 41-4E. This situation has been referred to as "*masked*" *granulocytosis*<sup>41</sup> and has been encountered in occasional patients with

chronic infection, Hodgkin's disease, or polycythemia vera,<sup>35</sup> in the early phase of post-endotoxin neutrophilia<sup>33</sup> and in patients with induced skin inflammations.<sup>41</sup>

A single injection of hydrocortisol produces a transient neutrophilia of a few hours' duration (Fig. 41-5) that is due partly to an increased rate of neutrophil release from the bone marrow and partly to a decrease in egress of cells from the blood.<sup>37</sup> Continued oral administration of a glucocorticoid such as prednisone results in a stable neutrophilia with an enlarged TBGP. The  $t_{1/2}$  values are normal or slightly prolonged (9 to 13 hours) and neutrophil production and destruction (GTR) are maintained at normal rates.<sup>33</sup> The movement of neutrophils into sites of inflammation nevertheless remains decreased.<sup>40,39</sup> It is postulated that this may in part explain the apparent increased susceptibility to infection of patients receiving steroids and perhaps contributes to the beneficial effects of steroids in gout, collagen vascular disease, and hypersensitivity reactions.

Fewer studies have been carried out in neutropenic states because of technical difficulties. Nevertheless, it is evident that patients may have a shift neutropenia or a true neutropenia. In "shift" or "pseudoneutropenia" the blood neutrophil concentration is decreased, but the TBGP remains normal (Fig. 41-4C).<sup>35,40</sup> Shift neutropenia may be transient in character, as after endotoxin<sup>33</sup> or nicotinic acid<sup>36</sup> injection, or constant, as in chronic neutropenic states.<sup>38</sup> However, in most patients with neutropenia there is a reduction in TBGP size; this is *true neutropenia*, the size of both the CGP and MGP being decreased (Fig. 41-4G, H, and I) although not always proportionately so.<sup>38,49</sup> On the basis of kinetic studies, true neutropenia may result from decreased cell production with normal cell survival in the blood or from decreased cell survival (short  $t_{1/2}$  values).<sup>38,42,48,52</sup> Neutropenia due to decreased cell production is associated with marrow suppression by drugs or x-ray therapy,<sup>38,52,60</sup> malignant disease involving the bone marrow such as leukemia and multiple myeloma,<sup>38,43</sup> and occasional cases of lupus erythematosus or cirrhosis.<sup>38</sup> Neutropenia

Fig 41-5 The effects on the concentration of blood leukocytes of intravenous endotoxin compared with those of intravenous hydrocortisol. At time zero a normal subject was given (A) 8 µg of endotoxin intravenously, one week later the same subject was given (B) 200 mg of hydrocortisol phosphate intravenously.

due to increased cell destruction (short  $t_{1/2}$ ) may be associated with subnormal, normal, or increased neutrophil production in the marrow<sup>38,52</sup> and occurs in a variety of diseases, including cirrhosis with splenomegaly, lupus erythematosus, megaloblastic anemia, viral infection, Felty's syndrome, and other conditions.<sup>38,52</sup> The mechanisms by which cell survival is shortened and marrow production is altered in these states are not yet clear. In some patients, splenectomy has alleviated both the neutropenia and the frequent infections,<sup>107</sup> and the kinetic picture has returned toward normal.<sup>33,52</sup>

#### Estimation and Significance of Quantitative, Qualitative, and Morphologic Changes in Blood—Neutrophils in Disease

Long before kinetic and other studies provided greater insight regarding the pathologic

physiology of alterations of leukocytes in disease, experienced clinicians, by paying careful attention to quantitative and qualitative changes in leukocytes, were able to draw inferences of value in judging the nature of disease processes and their probable outcome. It was recognized, for example, that pyogenic bacteria usually call forth a neutrophilic response the magnitude of which depends on: (1) the virulence of the organism, (2) whether the infection is localized or widespread, and (3) the patient's ability to respond to the process. Thus neutrophilia was noted to be minimal or absent when the pyogenic infection was mild, while a brisk neutrophilia in a patient with serious infection indicated good resistance. In serious infection, successive detailed blood examinations were found to be of considerable value prognostically; eg, a low or falling count and a shift to the left with metamyelocytes and myelocytes appearing in the blood suggested exhaustion of marrow neutrophil reserves and a poor outcome.<sup>89,127</sup>

It was also recognized that toxic granulation (see below), cytoplasmic vacuoles,<sup>223</sup> diffuse cytoplasmic basophilia,<sup>224</sup> pyknotic areas in the nucleus,<sup>214</sup> and Dohle bodies<sup>229</sup> (see below) appear in severe infections and have grave prognostic significance. The presence of one or more of these changes<sup>199,214,221,231</sup> and especially of toxic granulation suggests the development of bacteremia and generalized infection as opposed to a localized one.<sup>199,224</sup> The *degenerative index* was introduced as a means of quantitating these changes.<sup>199,214,224</sup> An index greater than 50% (more than 50% neutrophils exhibiting toxic granulation) suggested severe infection and a grave prognosis; serial indices were found to be more informative than changes in leukocyte concentration or a left shift in the differential count.<sup>199</sup> More recently the presence of *cytoplasmic vacuoles* in blood neutrophils has been found to correlate well with the presence of bacteremia<sup>231</sup> and impaired granulocyte function.<sup>223</sup>

Kinetic studies have confirmed many of these clinical impressions,<sup>50</sup> and have demonstrated that the magnitude of the blood

neutrophil concentration is affected both by the rate of cell inflow from the marrow and the rate of cell egress into the tissues. They indicate, furthermore, why the magnitude of the neutrophil count is not by itself a wholly reliable index of prognosis. For example, in a patient with extensive infection who is responding well, a high blood neutrophil count results because cell inflow from a well-stocked marrow is exceeding cell outflow into the infected tissues. On the other hand, very high neutrophil counts ( $40.0 \times 10^3$  cells/l) occur in the agonal state and appear to be related to terminal rises in plasma steroid level<sup>229</sup>; here the high steroid level enhances mobilization of marrow neutrophils, but blocks their egress from the blood into the tissues.<sup>37</sup> In the neutropenia seen in overwhelming infection there is a continued need for and egress of cells into the tissues, but the exhausted marrow is unable to supply enough cells to keep up with the demand.<sup>50</sup>

In contrast to the pyogenic infections, leukopenia and neutropenia are commonly associated with some bacterial (page 1270) and viral infections (page 1271) and are not necessarily attended with a poor outcome. The pathophysiology in these conditions is yet to be studied, however. Since, in typhoid fever, chills produced by cold baths resulted in neutrophilia,<sup>141</sup> it seems possible that the neutropenia characteristic of typhoid fever reflects a shift of neutrophils into a large marginal neutrophil pool; however, this remains to be proved.

### Toxic Granules (Fig. 41-6) (Plate XVI)

Toxic granules were thought either to reflect a disturbance in neutrophil maturation with persistence of azurophilic granules even into mature cell stages<sup>199</sup> or to be the result of absorption of toxic agents that resulted in new abnormal granule formation.<sup>187</sup> Since toxic granulation, vacuole formation, increased cytoplasmic basophilia, and other changes can be produced by incubating neutrophils in vitro,<sup>187</sup> it seemed highly probable that these changes are induced in vivo in already formed neutrophils, and perhaps rep-

resent phagosomes or autophagic vacuoles. However, electron microscopy and histochemical studies now have shown that toxic granules are azurophilic (primary) granules that are peroxidase positive and are more readily stained than are the granules in normal cells.<sup>198</sup> An increase in non-granule-associated acid phosphatase in cells containing toxic granules suggests that there has been some release of azurophilic granule enzymes.<sup>198</sup> This finding and the increase in alkaline phosphatase activity that may also be seen in infection (see below) imply that toxic neutrophils are "stimulated" perhaps in a manner similar to that in which cells involved in phagocytosis or reacting to treatment with endotoxin are stimulated (page 259).

### ***Döhle Bodies (Fig. 41-6)***

Döhle bodies are discrete, round or oval areas seen in the peripheral portions of the cytoplasm of neutrophils; they stain sky-blue with Romanowsky dyes and have been identified by electron microscopy to be lamellar aggregates of rough endoplasmic reticulum (Fig. 41-6E).<sup>198</sup> They were first described as present in patients with scarlet fever but are also found to be associated with many infections, severe burns,<sup>229</sup> exposure to cytotoxic agents,<sup>198</sup> and uncomplicated pregnancy.<sup>150</sup> They are similar to and must be differentiated from May-Heggelin bodies (page 1322 and Fig. 42-4).

### ***Tests for Enzyme Activity***

Since there is increased intracellular enzyme activity in association with phagocytosis (page 259), measurements of such activities may prove clinically useful. Thus, in the *NBT dye test* the spontaneous reduction of colorless, nitro blue tetrazolium dye to blue-black formazan deposits within neutrophils demonstrates the presence of NADH-oxidase activity (page 1328 and Fig. 42-6). In normal persons, less than 10% of blood neutrophils are NBT positive.<sup>196,211</sup> In most patients with bacterial infections and bacteremia, more than 10% of neutrophils are NBT posi-

tive, while in those with a wide variety of other febrile illnesses, including viral infections, tuberculosis, and post-perfusion syndrome, normal values have been found.<sup>181,182,196,210</sup> Thus, the NBT test may be useful in differentiating certain types of bacterial infection from other illnesses. It is also helpful in the diagnosis of chronic granulomatous disease (page 1328).

*Leukocyte alkaline phosphatase (LAP)*<sup>169</sup> is capable of hydrolyzing phosphorus from a wide variety of phosphomonoesters. Activity of this enzyme has been shown by both histochemical (Plate XV) and biochemical methods to be moderately increased in neutrophil leukocytes in physiologic leukocytosis, pyogenic infection, and leukemoid reactions, but it also is increased in Hodgkin's disease, myocardial infarction, pregnancy, undelivered hydatidiform mole (in contrast to choriocarcinoma),<sup>186</sup> and in "stressful" conditions, and can be increased by the administration of ACTH and adrenocorticosteroids to normal individuals. As a rule, in polycythemia vera (in contrast to secondary forms of polycythemia),<sup>208</sup> some cases of myelofibrosis, and idiopathic thrombocytopenia greatly increased activity is found,<sup>193</sup> whereas low levels of activity usually characterize chronic myelocytic leukemia, but this is not always the case.<sup>191,225</sup> Remission may be associated with a return to normal values. Higher than normal values were reported in acute lymphoblastic leukemia in contrast to zero values in acute myeloblastic leukemia. In chronic lymphocytic leukemia, lymphosarcoma, and reticulum cell sarcoma, values within or just above or below the normal range were found.<sup>189</sup>

Low levels of LAP also have been reported in individuals with paroxysmal nocturnal hemoglobinuria and in a few with myelofibrosis. They have been found associated with infectious mononucleosis, pernicious anemia, aplastic anemia, thrombocytopenic purpura, and sarcoidosis,<sup>169</sup> as well as with the metabolic disorder, hypophosphatasia. Androgenic hormones may inhibit this enzyme.<sup>219</sup> LAP is increased in mongolism, a condition associated with trisomy of chromosome 21.<sup>154</sup>

<sup>a</sup>SC, subcutaneously; IM, intramuscularly; IV, intravenously; p.o., orally

It has been suggested that alterations in LAP may be due to loss or inactivation of a regulator (modifier) rather than of the structural gene for LAP.<sup>137</sup> The induction of LAP formation in CML leukocytes in diffusion chambers implanted in mice is compatible with this thesis.<sup>168</sup>

Electrophoretic differences in the LAP of normal and chronic myelocytic leukemic leukocytes have been reported.<sup>217</sup>

#### Evaluation of the Functional Status of the Neutrophil System

With the widespread use of potent marrow-suppressing drugs of all kinds, in particular those used in the treatment of malignant disease, it has become more important than ever before to be able to assess the functional capacity of the neutrophil system. The measurement of blood neutrophil concentration and the proportions of the different types of cells, as well as the estimation of bone marrow cellularity and the myeloid:erythroid ratio, provide relatively crude estimates of the functional status of the neutrophil system; these measurements also are subject to large sampling errors.<sup>38,183</sup> Furthermore, it has been observed that, except in patients receiving steroid therapy<sup>158</sup> or in patients showing

defects in bactericidal capacity, as for example in some patients with Felty's syndrome,<sup>122,135</sup> little difficulty with infection is observed until concentrations of less than  $0.5 \times 10^9$  neutrophils/l occur.<sup>160</sup> Even at still lower levels, little or no difficulty may be encountered if other defense mechanisms are intact or if the patient can mobilize a few neutrophils at sites of inflammation.<sup>174</sup> For these reasons, several techniques have been described as a means for measuring marrow granulocyte reserves (MGR) with greater accuracy than that provided by crude estimates. These involve the injection of agents such as bacterial endotoxin or adrenal and other steroids that produce blood neutrophilia (Table 41-3). A typical normal response is shown in Figure 41-5; it can be seen that endotoxin and hydrocortisol both produce neutrophilia, but the magnitude and timing of the responses are somewhat different. Furthermore, the effect on leukocytes other than neutrophils differs with each compound. Etiocannabinolone produces neutrophilia, but does not affect other leukocytes.<sup>192</sup> The neutrophil response to the test agents is reduced in patients who have received chemotherapy or extensive x-ray therapy, or in whom the marrow is infiltrated by leukemia, myeloma cells, or other abnormal cell popula-

tions.<sup>38,183,192</sup> In some of these situations the MGR may be reduced even in the presence of normal blood leukocyte and differential counts. Detection of a decreased MGR is useful in predicting an increased risk of severe drug toxicity in cancer patients.<sup>183,185,192</sup>

Methods for assessing the ability of leukocytes to migrate *in vivo* into areas of induced inflammation such as skin windows,<sup>15</sup> skin blisters,<sup>2</sup> or plastic chambers placed over skin abrasions<sup>16</sup> also have been described. A decrease in cell migration into such lesions occurs in patients receiving prednisone<sup>15,163</sup> and may partially explain the increased susceptibility of these patients to infection. Abnormal migration is also seen in some diabetics, in patients in shock,<sup>167</sup> in those with leukemia,<sup>39</sup> those having a variety of leukopenic states, and when ethanol is ingested.<sup>167</sup> Young myeloid forms are less able to migrate into the induced lesions than are more mature forms.<sup>39</sup>

In addition to the above *in vivo* evaluations of the neutrophil system, a variety of *in vitro* methods have been devised to assess the ability of neutrophils to respond to chemotactic stimuli<sup>106</sup> and to phagocytize bacteria, fungi, and other particles,<sup>223a</sup> or kill them once they are ingested. The micropore diffusion chamber system<sup>165</sup> can be used to evaluate the ability of neutrophils to respond to known chemotactic stimuli. Cellular defects in response to chemotactic stimuli have been described in patients with adult rheumatoid arthritis, diabetes mellitus, disseminated lupus erythematosus, polymyositis,<sup>156</sup> Chediak-Higashi syndrome (see Chapter 42), and the "lazy leukocyte" syndrome.<sup>206</sup> Serum inhibitors<sup>227</sup> or deficiency of serum factors (complement and others)<sup>152,205,230</sup> have been described. Such defects apparently are common in cirrhotic patients.<sup>177</sup>

Phagocytosis has been measured by incubating cells with particles under a variety of conditions; the proportion of cells ingesting organisms, the mean number ingested per cell,<sup>166</sup> and the total number of particles ingested can be measured. Also the disappearance of viable bacteria or latex particles

from the medium or the uptake of radioactive bacteria by cells can be measured.<sup>179,200</sup> To date no clear defect in the cellular component of phagocytosis has been identified, perhaps because so serious a defect might be lethal, but decreased phagocytosis due to impaired opsonization of particles occurs in acquired hypogammaglobulinemia<sup>212</sup> and perhaps also in hereditary agammaglobulinemia and complement deficiency states.<sup>152,202</sup> Decreased phagocytic activity was reported in neonates and was thought to be related to decreased opsonization and to cellular factors,<sup>204</sup> but other workers have found phagocytic activity to be normal in neonates although they described a transient bactericidal defect that disappeared after 12 to 24 hours.<sup>171</sup> Still other studies have demonstrated increased metabolic activity of leukocytes in the newborn.<sup>212</sup> These discrepancies may be more apparent than real or may reflect the use of different techniques; their resolution awaits further study.

Leukocyte function can also be evaluated by measuring one or more of the metabolic events that are associated with phagocytosis and bacterial killing<sup>222</sup> or by determining the presence of viable intracellular organisms.<sup>172</sup> Defects in bactericidal function have been studied primarily in hereditary and familial states (see Chapter 42). However, decreased bactericidal activity is reported in severely burned patients and appears to be related to decreased content of lysosomal enzymes<sup>151</sup>; phagocytosis and degranulation were normal. The possibility of defects in bactericidal capacity has not yet been explored extensively, but none have been reported in alcoholics.<sup>177</sup> Since a number of pharmacologic and other agents are known to affect leukocyte metabolic and microbicidal functions (eg, vitamin A, steroid hormones, phenylbutazone, and colchicine<sup>193</sup>), such studies will have to be carefully controlled.

## The Eosinophil Series

Eosinophilia refers to an increase in the number of eosinophilic leukocytes above normal ( $>0.7 \times 10^9/l$ ) if calculated from the

total leukocyte and differential count (see Table 6-4, page 242) and  $>$  about  $0.2 \times 10^9/l$  if determined by absolute counting methods<sup>305</sup> (Chapter 6, page 263).

During infections in which neutrophilia occurs, eosinophils are generally reduced in number or disappear entirely, and, in animals with parasite-induced eosinophilia, infection leads to rapid disappearance of blood eosinophils.<sup>308</sup> The sudden disappearance of eosinophils has been attributed, without conclusive proof, to adrenal corticosteroid activity. Recovery from the infection is often heralded by a return of blood eosinophils.

#### Causes of Eosinophilia (Table 41-4)

**ALLERGIC DISORDERS.** In allergic disorders, usually the eosinophilia is moderate ( $4$  to  $11\%$ , total count  $0.2$  to  $1.5 \times 10^9$  cells/l), but in some instances it may be much higher, eg, in bronchial asthma,  $55.0 \times 10^9$  leukocytes/l with  $62.5\%$  eosinophils<sup>297</sup>; in angioneurotic edema, leukocyte counts as high as  $44.0 \times 10^9/l$  with  $27$  to  $85\%$  eosinophils.<sup>307</sup> Eosinophils are usually abundant in nasal discharges,<sup>271</sup> sputum, and skin wheals<sup>298,299</sup> of allergic individuals. In a patient with fatal bronchial asthma a large preponderance of eosinophils was found in the bone marrow and massive infiltrations were present in the myocardium.<sup>267</sup> Smoking has been reported to cause eosinophilia.<sup>326</sup>

Eosinophilia due to nitrofurantoin, par- amino salicylic acid, sulfonamides, and several other drugs<sup>279,283</sup> has been reported. Marked eosinophilia was observed in a patient with iodide sensitivity.<sup>290</sup> It is also noted after gold therapy for rheumatoid arthritis.<sup>315</sup>

**SKIN DISEASES.** The highest and most constant eosinophilia ( $10$  to  $60\%$ , sometimes with leukocytosis) has been observed in pemphigus and in dermatitis herpetiformis. Eosinophilia has been found in association with exfoliative dermatitis, psoriasis, pruritus, prurigo, eczema, dermatitis venenata, ichthyosis, mycosis fungoides, pityriasis rubra, facial granulomas,<sup>268</sup> and scabies. Its develop-

Table 41-4. Causes of Eosinophilia

- 1 Allergic disorders bronchial asthma urticaria, angioneurotic edema, hay fever, some instances of drug sensitivity
- 2 Skin diseases especially pemphigus and dermatitis herpetiformis
- 3 Parasitic infestations especially parasites that invade the tissues, eg. trichinosis, echinococcus disease, less regularly in intestinal parasitism
- 4 Loeffler's syndrome
- 5 Pulmonary infiltration with eosinophils ("PIE syndrome")
- 6 Tropical eosinophilia
- 7 Certain infections, eg. scarlet fever, chorea, erythema multiforme
- 8 Certain diseases of the hematopoietic system chronic myelocytic leukemia polycythemia vera, pernicious anemia, Hodgkin's disease, following splenectomy
- 9 Malignant disease of any type, especially with metastases or necrosis
- 10 Following irradiation
- 11 Miscellaneous disorders perianteritis nodosa, rheumatoid arthritis sarcoidosis, certain poisons, etc
- 12 As an inherited anomaly
- 13 Idiopathic

ment in such cases may depend on whether or not there is an allergic component; the degree of eosinophilia often appears to vary with the extent of involvement.

**PARASITIC INFECTIONS.** Parasites that invade tissues cause the most pronounced eosinophilia. A striking example of this is infection with *Trichinella spiralis*. Eosinophilia appears one to two weeks after ingestion of infected food and reaches a peak level at the end of the third week. Fluctuating eosinophilia then persists for six months or more and in some instances for years. Values as high as  $85\%$  with absolute eosinophil levels of  $15.0 \times 10^9/l$  have been found. It is noteworthy, however, that eosinophilia may be absent throughout the infection, and in severe fatal disease it is generally absent.<sup>318</sup> Studies of experimental trichiniasis in rats have shown that the eosinophilic response requires the presence of intact parasites in sufficient numbers and distribution to produce a wide-

spread intense inflammatory reaction (the injection of homogenized larvae intravenously or intact larvae subcutaneously or intramuscularly did not produce eosinophilia). It has also been found that thymus-derived lymphocytes play an essential role as mediators of the eosinophilia.<sup>252</sup>

In *echinococcosis*, eosinophilia is usually mild but occasionally it is pronounced. It is most likely to occur when slow leakage of cyst fluid into the tissues is occurring.<sup>292</sup> When suppuration occurs, eosinophilia disappears and neutrophilia develops. In amebic abscess of the liver, eosinophilia is not found, neutrophilia being common.<sup>300</sup> In the early stages of *cysticercosis*, moderate eosinophilia occurs, but this disappears when encystment takes place.<sup>275</sup> In *coccidioidal granuloma*, eosinophilia is sometimes found,<sup>321</sup> and it has been observed in human *toxoplasmosis*<sup>270</sup> and in human *Toxocara canis* infections.<sup>256, 323</sup> In schistosomiasis (*S. mansoni*), eosinophilia may be marked during the incubation period.<sup>325</sup> The liver fluke, *Clonorchis sinensis*, causes marked eosinophilia.<sup>259</sup> Eosinophilia was observed in only a third of patients with filariasis<sup>263</sup> and has not been found in those with trypanosomiasis or with kala azar. From 50 to 85% eosinophils may be seen in the blood of persons with *gnathostomiasis*<sup>272</sup> and 78% was reported in *Capillaria hepatica* infection.<sup>270</sup>

In malaria the presence and degree of eosinophilia is variable. In one series of 100 patients who were convalescing from malarial attacks the absolute eosinophil count ranged from 0 to  $1.35 \times 10^9/l$ . Eosinophilia decreased as time progressed but lasted for at least eight weeks. A pronounced fall (about 50%) was observed 24 to 36 hours before the onset of malarial symptoms. After the febrile period, in patients given treatment, the eosinophilia regained its previous level in about 10 days.<sup>303</sup>

Intestinal parasitism is less regularly associated with eosinophilia than is parasitism in which tissue invasion is prominent, and the eosinophilia is never as marked. Eosinophilia of 10 to 30 and even 69%<sup>250</sup> may occur in infection with *Uncinaria*<sup>290</sup> or *Strongyloides*

during the early stage, in *Ascaris* infection,<sup>255</sup> and in *Taenia* infections during periods of diarrhea and abdominal pain. In hookworm infection, eosinophilia, present in all subjects parasitized, was greatest in those with a worm burden greater than 100, but there was no good correlation between the eosinophil percentage and the worm burden.<sup>293</sup> Infestations with *Enterobius vermicularis* (*Oxyuris*), *Trichocephalus trichiuris*,<sup>314</sup> various amebae,<sup>291</sup> and the flagellates are usually not associated with eosinophilia.

**LOEFFLER'S SYNDROME.** In Loeffler's syndrome, a mild illness, characterized by transient pulmonary signs and infiltrates and presumably due to a hypersensitivity reaction, eosinophilia is characteristic.<sup>277</sup> A clinical and blood picture identical to that described by Loeffler has been observed in patients with cutaneous helminthiasis or "creeping eruption" caused by *Ancylostoma brasiliense*<sup>332</sup>; in infection with *Clonorchiasis*,<sup>200</sup> with *Ascariasis*,<sup>255, 316</sup> with *trichinosis*, and with amebae; and in tuberculosis, brucellosis, pollinosis, and coccidiomycosis.<sup>231</sup> A similar and perhaps identical disorder in children that is characterized by asthmatic symptoms, pulmonary infiltrates, joint symptoms, urticaria, convulsions, hepatomegaly, eosinophilia, and hyperglobulinemia appears to be due to invasion by a variety of nematode larvae (*visceral larva migrans*).<sup>256</sup>

**"PIE SYNDROME."** A distinction has been made between the "PIE syndrome" (pulmonary infiltration with eosinophilia) and Loeffler's syndrome.<sup>283, 301</sup> Loeffler's syndrome has been considered an acute, self-limited condition with a benign outcome, while PIE syndrome is a more chronic, relapsing illness often accompanied by cough, dyspnea, fever, sweats, malaise, and other manifestations. It is characterized by pleomorphic bilateral pulmonary infiltrations and marked eosinophilia. A few of the patients have had pericardial involvement.<sup>283</sup> It should be noted that the distinction is a quantitative one and may not be real.

The PIE syndrome may be produced by various infections (tuberculosis, coccidiomy-

cosis, brucellosis, viral or bacterial pneumonia, bronchiectasis) or may accompany the numerous parasitic infections causing eosinophilia mentioned above.<sup>283</sup> It may also be a manifestation of neoplastic conditions (Hodgkin's disease, eosinophilic granuloma), allergic reactions including those due to a variety of drugs,<sup>283</sup> collagen disorders, and a few miscellaneous diseases. Adrenocorticosteroid therapy has been very effective in therapy when not contraindicated by the underlying disease.

**TROPICAL EOSINOPHILIA.** Under the title of "tropical eosinophilia," a condition of unknown cause was described in India and South-East Asia.<sup>276</sup> The syndrome begins gradually with malaise; weight loss; low-grade fever; a paroxysmal, dry, hacking cough; and physical findings similar to those of bronchial asthma. Leukocytosis and severe eosinophilia are present. The spleen may be palpable. Roentgenograms reveal diffuse bilateral mottling of the lung fields resembling the picture of acute miliary tuberculosis. After several weeks a chronic subfebrile state is reached in which coughing paroxysms and wheezing may persist but weight loss usually ceases. At this stage, increased bronchial markings like those seen in chronic bronchitis are noted in the roentgeograms.

Symptoms may persist for a long time unless arsenotherapy or diethylcarbamazine<sup>273</sup> is given, to which the response is striking. Tropical eosinophilia, like Loeffler's syndrome, probably represents a hyper-immune reaction and is attributed to a variety of parasites, mainly microfilariae.<sup>276</sup>

**OTHER INFECTIONS.** Moderate eosinophilia may occur in association with various infections. Most noteworthy is scarlet fever. In the early stage of this disease, eosinophilia of 5 to 8% and even 17% may be found, especially when constitutional symptoms are mild and the rash is slight.<sup>280</sup> In chorea, eosinophilia is common and may reach values as high as 26%.<sup>280</sup> It is of interest that eosinophilia occurs also in erythema multiforme but not in acute rheumatic fever in which erythema is not a complication.<sup>320</sup> It has been stated that

eosinophilia occurs in gonorrhea when the posterior urethra, epididymis, or prostate is involved. It has been reported in leprosy.<sup>293</sup>

**DISEASES OF THE HEMATOPOIETIC SYSTEM.** In chronic myelocytic leukemia an increase in all types of granulocytes usually occurs, and even when the proportion of eosinophils is not increased, the absolute number is high. In polycythemia vera eosinophilia is not unusual. In about 20% of patients with Hodgkin's disease a slight or moderate eosinophilia occurs. In rare instances, values as high as 90% have been recorded.<sup>327</sup> Following splenectomy that has been performed for any cause, mild eosinophilia together with lymphocytosis may replace the neutrophilia that first appears. This may persist for several months.

A few patients with marked eosinophilia, leukocytosis, and hepatosplenomegaly have been described in whom the clinical and postmortem pictures suggested the diagnosis of eosinophilic leukemia.<sup>288,298,320</sup> Pulmonary infiltration and myocardial and/or pericardial involvement have been present in many of these subjects; the differentiation of their illness from that due to the PIE syndrome and collagen vascular disease<sup>317</sup> has been difficult. Some would distinguish patients having eosinophilia in which most of the eosinophils were mature and who experienced long survival ("hypereosinophilic syndrome"<sup>285,319</sup>) from patients with increased numbers of blasts in the blood and marrow who survived only a few months. Symptoms in the latter group more closely approximate those due to leukemia<sup>258,320</sup> (page 1475) than do those in the former.

In pernicious anemia, eosinophilia up to 20 or even 60% may develop. This was particularly common following the use of uncooked liver for treatment. In sickle cell anemia, eosinophilia is found occasionally.

**MALIGNANT DISEASE.** Eosinophilia is noted in malignant disease of various types.<sup>289</sup> In over 2,000 patients with malignant tumors of all types, 0.5% exhibited eosinophilia.<sup>289</sup> The eosinophilia was thought to be associated with dissemination or tumor necrosis.<sup>289,312</sup>

In rats with transplanted lymphomas and associated eosinophilia, the eosinophilia was not due to increased cell production; rather, it seemed to result from prolonged eosinophil survival in the blood, possibly caused by blockage of normal emigration pathways.<sup>328</sup>

**IRRADIATION.** Eosinophilia has been reported in radiological workers and in patients following courses of irradiation over trunk areas.<sup>276a</sup>

**MISCELLANEOUS DISORDERS.** Eosinophilia has been noted in a miscellaneous group of disorders: *perianteritis nodosa* (in about 18% of subjects, with values as high as 84%)<sup>310</sup>; *rheumatoid arthritis* complicated by vasculitis and pleuritis<sup>312</sup>; extensive caseous tuberculosis of the lymph nodes<sup>305</sup>; ulcerative colitis<sup>322</sup>; and congenital cardiovascular malformation.<sup>306</sup> It has occurred as a benign, idiopathic condition in which leukocyte counts as high as  $138.0 \times 10^9$  cells/l were noted, 93% of the cells being eosinophils.<sup>287</sup> Allegedly it has followed poisoning by copper sulfate, by camphor, by pilocarpine, and by phosphorus.

**HEREDITARY EOSINOPHILIA.** Mild eosinophilia not associated with any of the conditions described above has been reported in about 19 families.<sup>292-313</sup> The condition is inherited as an autosomal dominant trait, is benign, and must be distinguished from eosinophilia of other causes.

**IDIOPATHIC EOSINOPHILIA.** In some patients with eosinophilia no cause can be found even after extensive evaluation.

## The Basophil Series<sup>345</sup>

Basophilic leukocytosis or basophilia refers to an increase in the number of basophilic leukocytes above normal (that is,  $>0.15 \times 10^9$  cells/l if calculated from the total leukocyte and differential count [Table 6-4, page 242] and  $>0.1 \times 10^9$  cells/l if counted directly) (page 266). The basophil concentration is increased in myxedema and is low in hyperthyroidism, during ovulation, in pregnancy,<sup>352</sup> and under conditions of

stress.<sup>347</sup> Basophil numbers may also be increased in ulcerative colitis,<sup>347</sup> chronic sinusitis, smallpox, chickenpox, following the injection of foreign protein,<sup>345</sup> and in some cases of nephrosis.<sup>241</sup> They are frequently increased in chronic myelocytic leukemia, polycythemia vera, myeloid metaplasia, following splenectomy, in some chronic hemolytic anemias, and in Hodgkin's disease.

Infiltration of basophils has been demonstrated in areas of contact dermatitis, apparently in response to an initial interaction between antigen and lymphocytes. Thus the basophil appears to be involved in certain types of delayed hypersensitivity,<sup>343</sup> and IgE appears to be an essential intermediate in the reaction.<sup>344</sup> Blood basophilia does not appear to accompany such local reactions. Estrogens and antithyroid drugs produce increased values,<sup>352</sup> while adrenal corticosteroids and ACTH produce a decrease<sup>346</sup> as do acute infection<sup>349</sup> and x-irradiation or chemotherapy.<sup>349</sup>

In *urticaria pigmentosa* and in *systemic mast cell disease*,<sup>350</sup> blood basophils are not usually or greatly increased, but mast cells may be increased in the bone marrow and they may also be seen in the blood (Chapter 49). The presence of progressive anemia, leukopenia, thrombocytopenia, and hepatosplenomegaly may suggest leukemia (page 1502), but a pigmented maculopapular rash and dermatographism are characteristic. There often is widespread skeletal disease and there may be a marked increase in serum histamine levels and decreased serum serotonin and hyaluronic acid; in the urine, chondroitin sulfuric acid B is found.<sup>340</sup>

## The Monocyte Macrophage Series

Monocytosis refers to an increase in blood monocytes above the upper limit of normal ( $>0.95 \times 10^9$  cells/l) (see Table 6-4).

### Causes of Monocytosis (Table 41-5)

**BACTERIAL INFECTIONS.** Monocytosis may be present in certain bacterial infections, in-

cluding actively progressing tuberculosis, subacute bacterial endocarditis, septicemia, syphilis, and brucellosis.<sup>368,367</sup> Infection by *L. monocytogenes* produces a marked mononuclear response (apparently both monocytic and lymphocytic<sup>368</sup>) in rabbits<sup>376</sup> and other animals, but rarely does so in man.<sup>370</sup>

The role of the monocyte in tuberculosis has been studied intensively.<sup>363,366</sup> It was shown that this cell plays an important part in the cellular reaction to the tubercle bacillus. The phospholipids of this organism are partially degraded within monocytes and macrophages and cause the transformation of these cells to epithelioid cells. The monocyte is thus the chief cell in new tubercle formation. This activity may be reflected in the blood, monocytosis being regarded as evidence of active extension of the tuberculous process.<sup>360,363</sup> In following tuberculous infection in animals or man the *monocyte: lymphocyte ratio* has proved useful.<sup>360,363,374</sup> The normal ratio is about 0.3, or less; in active tuberculosis the number of blood monocytes may increase to or exceed the number of lymphocytes. A ratio of 0.8 to 1.0 or higher indicates active exudation and an unfavorable prognosis. With healing the number of monocytes decreases, while the lymphocytes may increase, resulting ultimately in a return to the normal ratio.

In endocarditis caused by *Streptococcus viridans*, monocytosis may occur, as many as one third of the leukocytes being of this type.<sup>377</sup> Monocytosis may occur in the absence of leukocytosis and its magnitude is subject to great fluctuations.<sup>372</sup> Histiocytic cells (sometimes referred to as reticuloendothelial cells, macrophages, or transformed monocytes) (see Chapter 6, page 267) may be found in the blood as well. They occur in about 25% of patients with subacute bacterial endocarditis.<sup>369</sup> They may exhibit vacuoles (perhaps phagosomes) in their cytoplasm and have been seen to contain engulfed erythrocytes, neutrophils, or lymphocytes.<sup>367</sup> Histiocytes are more abundant in the first drop of blood obtained from the ear lobe than from the finger<sup>364</sup> and their presence should suggest endocarditis even in the absence of

Table 41-5. Causes of Monocytosis

- 1 *Certain bacterial infections* tuberculosis, subacute bacterial endocarditis, syphilis, brucellosis
- 2 *During recovery from acute infection* and from agranulocytosis, in "leukopenic infectious monocytosis"
- 3 *Many protozoal and rickettsial infections* malaria, typhus, Rocky Mountain spotted fever, trypanosomiasis, kala azar, Oriental sore
- 4 *Lymphoma, leukemia and other hematologic disorders* monocytic leukemia, Hodgkin's disease and other lymphomas, chronic myelocytic leukemia and "myeloproliferative" disorders, multiple myeloma, lipid storage diseases
- 5 *Malignancy* carcinoma of ovary, stomach, breast
- 6 *Collagen vascular disease* lupus erythematosus, rheumatoid arthritis
- 7 *Granulomatous disease* sarcoidosis, ulcerative colitis, regional enteritis
- 8 *Tetrachloroethane poisoning*

positive blood cultures.<sup>369</sup> An occasional histiocyte may be found in the blood in a variety of other disorders.<sup>365</sup>

**RECOVERY FROM ACUTE INFECTION.** Transient monocytosis may develop in patients recovering from acute infection; if complications such as empyema occur the monocytosis may persist.<sup>366</sup> Monocytosis also occurs in the recovery phase of agranulocytosis (page 1298).

Increased numbers of monocytes and mononuclear leukocytes have been reported in infants and young children with probable viral disease,<sup>380</sup> and in adults with *collagen vascular disease*, arthritis, and other inflammatory processes.<sup>371</sup> In the latter patients, the mononuclear cells exhibited enhanced ability to incorporate tritiated thymidine in their DNA, but it is not clear whether the cells were atypical lymphocytes (presumably participating in an immune response to their disease), monocyte precursors released in response to tissue injury, or both.

*Leukopenic infectious monocytosis* is the name proposed for a rare acute illness that often has been associated with necrotizing ulcerations of the mucous membranes and has been accompanied by normal or decreased leukocyte count, neutropenia, and monocyto-

sis.<sup>378,379</sup> The prognosis has been favorable in most cases, but deaths have occurred.<sup>378</sup> In many instances a history of drug ingestion was elicited, thus suggesting that this condition may be a variant of agranulocytosis. In some instances, however, drugs could not be clearly incriminated.<sup>379</sup>

**PROTOZOAL AND RICKETTSIAL INFECTIONS.** Monocytosis occurs in many protozoal and rickettsial infections such as *malaria*, *typhus fever*, and *Rocky Mountain spotted fever*. In kala-azar as many as 45% monocytes may be seen, but because of the leukopenia an absolute monocytosis is unusual.<sup>386</sup> In Oriental sore, trypanosomiasis, and in some patients with syphilis,<sup>381</sup> especially those having dementia paralytica,<sup>385</sup> monocytosis occurs.

**LYMPHOMAS AND HEMATOLOGIC DISORDERS.** Monocytosis is found in lymphomas and other hematologic disorders. The highest blood monocyte concentrations are seen in *monocytic leukemia*, but values greater than  $1.0 \times 10^9$  cells/l are found in about one third of patients with *Hodgkin's disease*,<sup>373</sup> and absolute monocytosis may also be seen in *reticulum cell (histiocytic) and other lymphomas*. Monocytosis may occur in *Gaucher's disease*,<sup>381</sup> *Niemann-Pick disease*, *Hand-Schüller-Christian disease*, *subacute and chronic myelocytic leukemia*, in other "myeloproliferative disorders," and in *multiple myeloma*.<sup>373</sup>

**MALIGNANT DISEASE.** In malignant neoplasms, such as carcinoma of the ovary, stomach, or breast, monocytosis is not uncommon<sup>373</sup> and may reflect some resistance to the tumor.

**COLLAGEN VASCULAR DISEASE.** Absolute monocytosis is present in over 50% of patients with collagen vascular disease.<sup>373</sup>

**GRANULOMATOUS DISEASES.** Monocytosis may be associated with granulomatous diseases such as *sarcoidosis*, and with *ulcerative colitis* and *regional enteritis*. It has been reported in patients with fever of unknown origin and in patients in whom no clear diagnosis could be established.<sup>373</sup>

**TETRACHLORETHANE POISONING.** Monocytosis has occurred in tetrachlorethane poisoning.<sup>375</sup>

## The Lymphocyte Series

Lymphocytosis refers to an increase in blood lymphocyte concentration above the normal level of  $4.0 \times 10^9$  cells/l (see Table 6-4), while lymphopenia refers to a decrease below  $1.5 \times 10^9$  cells/l. As already discussed (Chapter 2 and Fig. 2-11, page 58) the blood of infants and young children contains a higher proportion and concentration of lymphocytes than that of adults and these values gradually decrease toward adult values as maturation progresses.

### Causes of Lymphocytosis

**CERTAIN ACUTE INFECTIONS.** Lymphocytosis (Table 41-6) is rare during *acute bacterial infections* except in *pertussis*. In 63% of children with pertussis who were over six months old a lymphocyte concentration greater than  $11.0 \times 10^9$  cells/l was observed during the first 2 weeks of infection; during the third week, 81% had lymphocytosis, after which this finding was less common. Lymphocytosis was seen in only 20 to 25% of children with pertussis who were younger than six months of age.<sup>410</sup> Usually the total leukocyte count in pertussis is about  $20.0 \times 10^9$ /l and the lymphocytes constitute 60% or more of this number<sup>421</sup>; however, the lymphocytosis may exceed  $50 \times 10^9$  cells/l in 4 to 21% of the subjects,<sup>410,711</sup> these high values usually

Table 41-6. Causes of Lymphocytosis

1. Certain acute infections: pertussis, acute infectious lymphocytosis, infectious mononucleosis, infectious hepatitis
2. Certain chronic infections: brucellosis, tuberculosis, secondary and congenital syphilis
3. Hematopoietic disorders: lymphocytic leukemia, chronic and acute, some cases of lymphosarcoma, heavy chain disease
4. Relative lymphocytosis may be seen in exanthems, after the initial stage, especially in mumps and German measles, during the stage of convalescence from acute infections, in thyrotoxicosis, in most conditions associated with neutropenia

being associated with complications (see Experimental Production of Leukemoid Reactions, page 1303). The lymphocytes are of the small, mature type.

**Acute infectious lymphocytosis** is a benign disease having an incubation period of 12 to 21 days. It is characterized by lymphocytosis and is seen most frequently in children although it has been reported in young adults as well. The onset is marked by varying degrees of constitutional reaction. No symptoms whatever were observed in most of the patients, whereas, in one series,<sup>392</sup> fever occurred in 30% and gastrointestinal symptoms such as diarrhea (5%) and vomiting (rare) were experienced by a few of the subjects. Occasionally abdominal symptoms and signs severe enough to suggest an acute surgical condition have been observed.<sup>392,417,422</sup> In other subjects, upper respiratory symptoms, signs of central nervous system involvement, or skin rash has been noted.<sup>418,422</sup> Lymphadenopathy and splenomegaly are usually absent. The lymphocytosis persists for three to seven weeks and consists of predominantly normal adult lymphocytes; the average peak value is  $34.0 \times 10^9/l$ ,<sup>392</sup> but values as high as  $117 \times 10^9$  cells/l have been reported.<sup>417</sup> Because eosinophilia of marked degree (average  $2.3 \times 10^9/l$ ) has been observed in many of the patients, the possibility of parasitism as the cause of this condition has been entertained.<sup>392,407</sup> No anemia or thrombocytopenia has been observed. The bone marrow shows some increase in lymphocytes (30 to 40%). Lymph node biopsy in two instances revealed nondiagnostic degeneration of the follicles and proliferation of the sinus reticuloendothelium.<sup>422</sup> The heterophil agglutination test has given uniformly negative results. An increase in spinal fluid lymphocytes has been reported in occasional subjects. The disease appears to be infectious and moderately contagious, but as yet no definite etiologic agent has been clearly incriminated. Both an adenovirus<sup>413</sup> and a Coxsackie A virus<sup>407</sup> have been suggested as etiologic agents. EB virus and cytomegalovirus do not appear to be involved.<sup>395</sup>

Lymphocytosis is characteristic of *infec-*

*tious mononucleosis*, but, in contrast to pertussis and infectious lymphocytosis, many atypical and large lymphocytes are present in the blood (see Chapter 43). Lymphocytosis with many atypical cells is noted also in the *post-transfusion syndrome* (probably cytomegalovirus disease, see Chapter 43) and may be found in infectious hepatitis as well.<sup>411</sup> As already mentioned, atypical lymphocytes and monocytes may sometimes be difficult to differentiate and the numbers of both may be moderately increased in a variety of disease states (see page 1287).

**CHRONIC INFECTIONS.** Occasionally, absolute lymphocytosis is found in association with certain chronic infections such as *brucellosis*<sup>398</sup> and with healing tuberculosis (page 1287). In the secondary stage of syphilis, lymphocytosis may occur and in *congenital syphilis* leukocyte counts as high as  $60 \times 10^9$  cells/l, the cells consisting mainly of lymphocytes, have been reported.<sup>399</sup>

**HEMATOPOIETIC DISORDERS.** Lymphocytosis is characteristic of chronic lymphocytic leukemia (see Chapter 49) and is present in most patients with acute lymphoblastic leukemia (see Chapter 47). It may also be found in some patients with non-Hodgkin's lymphomas (Chapter 51) and lymphocyte-like cells are present in the blood of patients with heavy chain disease (Chapter 53). In all of these conditions, lymphoblasts and intermediate and atypical lymphocyte forms are present in the blood in variable numbers.

**RELATIVE LYMPHOCYTOSIS.** During convalescence from acute infections, lymphocytosis is said to be common,<sup>415</sup> but such lymphocytosis usually is relative rather than absolute. The same appears to apply to German measles<sup>406</sup> and to mumps, in which 44 to 68% of the leukocytes may be lymphocytes<sup>423</sup> but the associated leukopenia results in normal absolute concentrations. Relative lymphocytosis also occurs in most conditions associated with neutropenia.

In *thyrotoxicosis*, Kocher (1908) described leukopenia, due to a reduction mainly of granulocytes, with relative and absolute lym-

phocytosis and moderate eosinophilia. However, these changes are inconstant, slight in degree, and are not reliable indices of prognosis or response to therapy.<sup>400</sup> Lymphocytic infiltration of the thyroid gland is correlated with the degree of lymphocytosis, and hyperplasia of lymphoid organs such as lymph nodes and spleen may be associated.

From time to time, attention has been called to *morphologic variations in lymphocytes in disease*.<sup>427</sup> In response to stress, lymphocytes that are characterized by nuclear and cytoplasmic distortion and by more cytoplasm than is normally seen may appear in the blood of mice.<sup>401</sup> These cells are similar to the atypical cells seen in infectious hepatitis,<sup>111</sup> serum sickness, and chronic infection.<sup>401</sup> An increase in lymphocyte size has also been described in adrenal insufficiency and in hyperthyroidism, these changes disappearing after appropriate therapy.<sup>405</sup> *Binucleate lymphocytes* appear in the blood in increased numbers after small doses of irradiation. Normal values are less than 4 binucleated cells/10<sup>4</sup> lymphocytes. During the second week, after a single exposure to 20 rads, 4 to 13 binucleated cells/10<sup>4</sup> lymphs were seen, and, after 50 rads, 6 to 32 binucleated cells were observed.<sup>416</sup>

*Lymphocytopenia* is seen in most acute infections and illnesses including heart failure,<sup>408, 420</sup> pneumonia,<sup>420</sup> pancreatic necrosis,<sup>404</sup> active tuberculosis,<sup>420</sup> carcinoma of varied origin,<sup>420, 421, 425</sup> uremia,<sup>423</sup> the lymphomas<sup>423</sup> (especially Hodgkin's disease<sup>390, 411</sup>), lupus erythematosus and other collagen diseases,<sup>428</sup> agranulocytosis (page 1298), malaria,<sup>130</sup> some immunologic deficiency syndromes,<sup>414</sup> and in a number of patients with no apparent disease.<sup>428</sup> In heart failure,<sup>408</sup> and probably other acute illnesses, the lymphopenia appears to be due to elevated plasma cortisol levels; the mechanism in other conditions is not understood. In addition, a number of agents and experimental procedures produce lymphopenia. These include adrenal steroid administration (Fig. 41-5), x-irradiation,<sup>397, 398, 409</sup> some chemotherapeutic agents,<sup>393, 394</sup> antilymphocyte serum,<sup>402</sup> thoracic duct drainage,<sup>403</sup> and

neonatal thymectomy.<sup>390</sup> In experimental animals, moderate exposure to dry heat, sunlight, the short ultraviolet rays<sup>396</sup> (less than 30 nro), and roentgen rays<sup>412</sup> has, after an initial reduction in lymphocytes, been shown to cause a marked lymphocytosis that persists for several weeks.

## Plasma Cells

Plasma cells are rarely found in the blood and when present their significance is obscure. In rubella as many as 19% Türk and plasma cells have been observed,<sup>412</sup> while in scarlatina, measles, and chickenpox<sup>414</sup> these cells are less numerous.<sup>423</sup> Their number may be increased in serum reactions,<sup>393, 419</sup> multiple myeloma, benign lymphocytic meningitis,<sup>426</sup> skin diseases, and sometimes in infectious mononucleosis. In plasma cell leukemia, they are the predominating cells.

## Agranulocytosis and Drug-Induced Neutropenia

### History

In 1922, Werner Schultz<sup>462</sup> drew attention to a syndrome of unknown cause which he had observed especially in women of middle age, and which was characterized by severe sore throat, marked prostration, extreme reduction or even complete disappearance of the granulocytes from the blood, and, in rapid succession, sepsis and death. He considered this to be a clinical entity which he called agranulocytosis. A detailed report of a similar condition had been published by Brown<sup>454</sup> in 1902 and by Türk<sup>463</sup> in 1907. However, it was not until the description of six cases by Schultz that general interest in this disorder was aroused.

A great variety of names have been used in referring to the syndrome described by Schultz, eg, agranulocytic angina; idiopathic, malignant, or pernicious leukopenia; granulocytic hypoplasia. Here the term "agranulocytosis" will be used to refer to the acute symptom-complex described by Schultz,

ile the terms "neutropenia," "granulocytosis," and "leukopenia" are used to refer to changes in the blood.

### ology

Although the majority of cases of agranulocytosis have been reported in the United States and Europe, agranulocytosis has been observed in all parts of the world.<sup>550</sup> The disease makes its appearance everywhere in the form of isolated cases.

Relatively few cases were described between 1922 and 1929, but in the next five years many were reported.<sup>555</sup> In 1931, Acke<sup>457</sup> pointed out that the sudden appearance of cases of agranulocytosis corresponded with the introduction of certain 1-tar derivatives. The disorder was especially common in the countries in which such drugs were in great use, and those affected were chiefly women of good economic status, as well as nurses and other medical workers whom these drugs were easily accessible. Acke noted that a history of the use of one of the coal-tar derivatives was often obtained in cases of agranulocytosis. Shortly afterwards, several reports<sup>460,480,490</sup> appeared that incriminated aminopyrine (Pyramidon) as the offending drug. It was noted that the majority of patients who developed agranulocytosis were adults, usually past middle age.<sup>460</sup> In proportion to other causes, agranulocytosis was a relatively frequent cause of death among people over 40 years of age, whereas it was rare in those under 25 years of age. Satisfactory accounts of typical agranulocytosis were found in only nine children.<sup>460</sup> The incidence among females as compared with males was about 2 or 3 to 1.<sup>460</sup> In relation to aminopyrine, it was reported<sup>480</sup> that the mortality in six patients who continued the use of drugs containing aminopyrine was 100%, whereas in a group of eight patients who stopped taking aminopyrine, only two died. The increased incidence of agranulocytosis in Denmark until 1934 corresponded exactly with the increased use of aminopyrine.<sup>460</sup>

After 1934 the number of cases of agranu-

locytosis decreased. This coincided with the reduced sales of aminopyrine following reports of its injurious effects.<sup>460</sup> Later, however, as new drugs were introduced new cases appeared.<sup>477</sup> A pattern was repeated which has now become a familiar one. A new agent is described and in a few years it is widely used. At first it is hailed as being nontoxic; ultimately a report appears describing the development of agranulocytosis in association with its use. This is followed by another case, and another, and the circumstantial evidence becomes impressive. The drug loses popularity and is employed with more discrimination than before. The number of cases of agranulocytosis due to this agent decreases sharply, only to be replaced by other cases as new drugs are added to the therapeutic armamentarium.

With the sharp reduction in the use of aminopyrine and the consequent rarity of cases of agranulocytosis due to this cause, some physicians were led to assume that the potential harmful effects of this drug had been greatly exaggerated. The fallaciousness of this view became clear when an increasing number of cases of agranulocytosis, with a number of deaths, were recognized to be associated with the increasing popularity of dipyrone, a derivative of aminopyrine with the same pharmacologic effects and therapeutic indications.<sup>474</sup> Potentially harmful itself, this drug also was shown to produce granulocytopenia in a patient who had recovered from aminopyrine agranulocytosis.<sup>474</sup>

### Agents Occasionally Associated with the Development of Leukopenia and Neutropenia (Table 41-7)

A number of physical agents, chemicals, and drugs produce blood dyscrasias such as anemia (Chapters 14 and 56), thrombocytopenia (Chapter 34), neutropenia, and leukopenia or various combinations of these, including pancytopenia (Chapter 56). Leukopenia is probably the most common; 42% of the cases reported to the AMA registry of adverse drug reactions were of this type.<sup>450,461</sup> Leukopenia is due mainly to a

\*Drugs italicized are those most frequently associated with leukopenia

reduction in neutrophils, but, if severe, other leukocyte forms may be reduced as well. As discussed earlier (page 1272), some agents produce neutropenia and leukopenia in everyone to whom they are administered if given in sufficient dose (Table 41-2), and since they also frequently produce anemia and thrombocytopenia (ie, pancytopenia) they will be considered in Chapters 55 and 56. Other agents produce neutropenia unpredictably and in only a few of the patients exposed to them (Table 41-7). These will be discussed here.

**Pathogenetic Mechanisms**

Agents that are only occasionally associated with neutropenia presumably act via some inherent sensitivity to a drug or one of its metabolic products. Such drugs can be grouped in at least two categories, according to the changes that are usually observed and the possible mechanisms involved.

1. In some cases, usually after the patient has had intermittent and repeated exposure to a drug, an acute, apparently immunologically mediated, hypersensitivity reaction takes place with sudden disappearance of neutrophils from the blood (*abrupt-onset neutropenia*). For example, the agranulocytosis produced by aminopyrine is of this type as judged from the clinical observation that a small challenging dose given to patients who had recovered from an episode of agranulocytosis resulted in disappearance of all neutrophils from the blood in 6 to 10 hours<sup>453</sup> or less.<sup>459</sup> Additional observations of this

kind have been reported.<sup>450</sup> Transfusion of blood drawn from a sensitive patient three hours after receiving aminopyrine produced granulocytopenia in normal subjects within 40 minutes; the neutrophil concentration returned to normal in four hours. This patient's serum caused lysis of granulocytes in vitro in the presence of drug.<sup>456</sup> A second attack of agranulocytosis was produced by the intradermal injection of drug incubated with serum.<sup>455</sup> In another sensitive patient, leukocytotoxic and leukoagglutinating antibody (present in the IgG and IgM serum protein fractions) persisted in the blood for one year.<sup>481</sup>

Although, pathophysiologically, one would postulate that such acute developing neutropenia results from *rapid, immunologically mediated destruction* of neutrophils, the immunologic mechanisms are not clear. Lysis of granulocytes by the offending drugs has been difficult to reproduce in vitro and the diagnostic significance of the leukocyte agglutination test has been questioned.<sup>456,459</sup> It has been postulated that the offending drug alters the leukocytes or complexes with them as a haptene causing them to become antigenic and thereby inducing a cell specific antibody response. However, there is no clear evidence that the chemical combination of drug with granulocyte components leads to the cell no longer being recognized as "self."<sup>456</sup> Another possibility is that the drug (or a metabolite) serves as a haptene and combines with protein to form a complex antigen to which antibody is then formed. Soluble antigen-antibody complexes might then coat leukocytes and lead to their destruction by various means.<sup>456</sup> The finding that one such antibody reacted with either patient's or control leukocytes supports this hypothesis.<sup>481</sup> Reasoning by analogy with the immune hemolytic states, several types of immune cell damage might be expected to occur such as direct cell lysis, agglutination, or sequestration and destruction in the spleen or other sites, but these are as yet unsubstantiated.

2. In other patients, after several weeks of drug treatment, neutrophil concentration may

begin to decrease slowly and may reach such low levels that discontinuance of the drug is necessary (*slow or delayed onset neutropenia*). Not infrequently, however the neutrophil concentration may stabilize at a reduced level or may even return toward normal in the face of continued drug administration.<sup>554</sup> The granulocytopenia associated with phenothiazine administration, and perhaps also with thiouracil, hydantoins, and the sulfonamides, often develops in this way and is presumably due to *decreased cell production*. In the case of chlorpromazine, at least three weeks of drug therapy seem necessary before granulocytopenia develops, and the bone marrow is usually hypocellular at the time granulocytopenia appears. It has been shown in vitro that chlorpromazine inhibits nucleic acid synthesis by marrow cells both in sensitive subjects and in some patients not known to be sensitive to the drug.<sup>508</sup> Labeled DNA and RNA precursor uptake by marrow cells was shown to be reduced in susceptible patients.<sup>508,510,511</sup> A suggested explanation for the fact that neutropenia develops only in a minority of patients given chlorpromazine is that only subjects with a limited marrow proliferative potential are unable to overcome the delay in DNA synthesis produced by the drug and, as a consequence, develop granulocytopenia.<sup>510</sup>

It should not be concluded that the above mechanisms are mutually exclusive. Some drugs appear to produce either abrupt-onset neutropenia or slow-onset neutropenia, eg, sulfonamides or antithyroid drugs. The mode of onset, furthermore, may reflect prior sensitization that in turn reflects the more usual manner of administration of the drug in question, eg, intermittent use for analgesic purposes, as in the case of aminopyrine, or continuous use for longer periods, as is usually the case with sulfonamides or antithyroid drugs. Still other drugs may act by means other than immunologic ones, eg, as metabolic antagonists in susceptible individuals. The relative incidence of neutropenia apparently caused by drugs and reported to the AMA Council on Drugs is shown in Figure 41-7.

Fig. 41-7 Numbers of cases of leukopenia and agranulocytosis reported to Registry on Adverse Reactions, Council on Drugs, AMA grouped according to drug or type of compound (From Wintrobe,<sup>441</sup> courtesy of the author and *Journal of the Royal College of Physicians, London*)

### Analgesics and Sedatives

A wide variety of proprietary and prescription medications containing *aminopyrine* or slight chemical modifications of this drug have been marketed, often with names that disguise the contents (Table 41-7). All of these have been incriminated as causing agranulocytosis<sup>472,476,477</sup> and they account for perhaps 75% of reported cases.<sup>453</sup> The incidence of agranulocytosis due to *aminopyrine* is estimated to be about 1%.<sup>472,484</sup> although in some large series no cases were noted.<sup>472,486</sup>

Much less commonly, *phenacetin* (Acetophenetidin)<sup>450,477</sup> and *acetanilid*<sup>477</sup> have been incriminated. Although many of the preparations containing *aminopyrine* also contained barbiturates,<sup>490</sup> only rarely has good evidence been provided that *barbiturates* alone produce agranulocytosis.<sup>450,453,473,483</sup>

*Phenylbutazone* is closely related chemi-

cally to *aminopyrine*<sup>485</sup> and has caused rapidly developing<sup>450,453,483,488</sup> as well as slowly developing neutropenia.<sup>488</sup> The administration of *phenylbutazone* to patients known to be sensitive to *aminopyrine* did not produce neutropenia or agranulocytosis,<sup>485</sup> although cross reactivity has been demonstrated *in vitro*.<sup>491</sup> The neutropenia developing during the first four weeks of therapy with *phenylbutazone* is said to be preceded often by skin rash, whereas neutropenia developing after the fourth week is not.<sup>492</sup> No apparent relation between dosage and the onset of leukopenia has been noted, and the blood changes occur any time between the seventh and the sixtieth day of therapy and after ingestion of from 3.5 to 39.2 g. Neutropenia has developed four to six days after discontinuing the use of *phenylbutazone*, presumably because the drug is slowly metabolized and excreted and remains in the blood for as long as 10 to 21 days after

the last dose.<sup>482</sup> The incidence of neutropenia in association with use of this drug is uncertain. In some series an incidence as high as 0.6% was described<sup>479</sup> and many toxic side effects were recognized,<sup>482</sup> while others reported, especially when doses of less than 200 mg/day<sup>487</sup> were given, that little toxicity was experienced.<sup>478,487</sup> In New Zealand, an approximate incidence of 0.005% can be calculated from the amount of drug sold and the incidence of associated neutropenia.<sup>471</sup>

*Oxyphenbutazone* is said to have 40% more therapeutic effect<sup>478</sup> and less than half as much toxicity (all types) as phenylbutazone.<sup>478,487</sup> *Acetylsalicylic acid*, when used alone, has been associated with leukopenia in three instances.<sup>453</sup>

#### *Phenothiazines and Tranquillizers* (Table 41-7)

After the introduction of *chlorpromazine* in 1952, reports of "agranulocytosis" due to this drug began to appear. However, as mentioned earlier, it became apparent that the granulocytopenia associated with the use of chlorpromazine and related phenothiazines is of gradual onset, and readministration of a small dose of drug after recovery does not elicit an acute response like that seen following aminopyrine.<sup>509</sup> Neutropenia developed after the drug has been ingested in amounts of one to 52 g for periods of time varying from 13 to 171 days<sup>501</sup>; in 90% of subjects, neutropenia appeared during the first eight weeks of treatment.<sup>500</sup> Elderly Caucasian females seemed particularly susceptible,<sup>500,509</sup> and no case was seen in 1600 Negroes treated with chlorpromazine.<sup>503</sup>

The incidence of neutropenia was reported to be as high as 10.8% in a small group of elderly women treated with large doses of *mepazine*, but in other series of patients treated with this drug the incidence varied from 0.8 to 7%.<sup>500</sup>

The incidence of severe neutropenia in a large series of 6,200 psychiatric patients treated with a variety of the phenothiazine drugs was 1/1240 and transient mild leukopenia was seen in about one third of the

patients.<sup>506</sup> The neutropenia produced by phenothiazines appears to be due to suppression of marrow neutrophil production, as described above. Only rarely has a leukoagglutinin been found.<sup>503</sup> Several of the phenothiazines do not appear to produce neutropenia, eg, promethazine and methdilazine,<sup>506</sup> and in general it is believed that compounds with the highest potency per mg are least likely to produce neutropenia.<sup>507</sup>

*Meprobamate* also has been reported to cause leukopenia and agranulocytosis as well as other dyscrasias<sup>453,502</sup> on occasion.

#### *Sulfonamides (Antibacterial)*

Severe neutropenia has been reported in association with the use of a number of antibacterial sulfonamide drugs (Table 41-7). The incidence appears to be about 0.5 to 1%,<sup>523,527</sup> and neutropenia usually has developed after the drug had been given for a few days and in a substantial dose, eg, 40 to 50 g of sulfanilamide or sulfapyridine given over a period of 7 to 33 days.<sup>477,521,527</sup> However, severe neutropenia has occurred after much smaller doses (eg, 4 g), and sulfapyridine has been reported to have higher toxicity than sulfanilamide and sulfathiazole.<sup>527</sup> The association of skin rashes, fever, and allied manifestations, and the appearance of neutropenia after a few days of therapy,<sup>527</sup> or occasionally after intermittent therapy,<sup>530</sup> suggest a possible immunologic mechanism, but no clear case of a precipitous drop in blood neutrophils after exposure to a single small dose of drug has been reported.<sup>522,527</sup> A leukocyte antibody has been detected in one or two patients,<sup>522,528</sup> and it is suggested that an antibody activated by drug may act chiefly on marrow precursor cells to interfere with cell production.<sup>522</sup>

#### *Sulfonamides (Non-Antibacterial)*

Cases of neutropenia associated with antidiabetic and diuretic sulfonamide drugs<sup>521,529,526,528</sup> (Table 41-7) are rare, particularly considering the widespread use of these agents. The neutropenia appears to

come on after one of these drugs has been used for a considerable time. A leukoagglutinin was reported in one patient.<sup>525</sup>

### Antithyroid Drugs

In association with the administration of thiouracil the leukocyte count decreased to less than  $3.0 \times 10^9$  cells/l with slight to marked neutropenia in 3.4% of 1091 patients taking this agent.<sup>557</sup> Fever and infection in association with severe neutropenia occurred in 1.7% of these patients, and the death rate in those developing agranulocytosis was 26%.<sup>557</sup> Very similar findings have been reported by others.<sup>554, 558, 562</sup> The leukocyte count usually decreased only after four to eight weeks of treatment in previously untreated patients,<sup>557, 558</sup> but leukopenia was seen as early as two weeks after restarting the drug in patients who had taken it previously.<sup>557</sup> In a few of the patients the readministration of a single small dose of the drug was followed by a rapid fall in neutrophil concentration and/or the reappearance of toxic symptoms such as malaise, fever, and chills.<sup>559, 565</sup> In some patients taking thiouracil, moderate leukopenia developed but the leukocyte count then returned to normal with continued therapy.<sup>559, 565</sup>

Leukopenia has been reported to occur in 4% of patients treated with methylthiouracil and about 1% of patients developed agranulocytosis.<sup>559</sup> Others have reported a higher incidence of reactions.<sup>549</sup> Propylthiouracil appears to be somewhat less toxic with leukopenia, occurring in only about 1.5% and agranulocytosis in 0.5% of patients treated.<sup>551</sup> Antibodies against leukocytes were reported in patients sensitive to this drug.<sup>556, 561</sup> Methimazole therapy was associated with leukopenia in 2% and agranulocytosis in 1% of persons treated with this drug.<sup>553</sup> Carbimazole is thought to be one of the least toxic of the antithyroid drugs,<sup>552, 560</sup> particularly in regard to its effects on leukocytes,<sup>552</sup> but it has not been approved for use in the United States.

### Anticonvulsants

Anticonvulsants have been reported to cause leukopenia and neutropenia as well as thrombocytopenia or aplastic anemia. The incidence of slowly developing neutropenia in patients taking trimethyloxazolidine (Tridione) was as high as 6.3%, while 2% of patients receiving diphenylhydantoin developed mild leukopenia.<sup>574</sup> Other case reports of neutropenia associated with the use of several of the anticonvulsants can be found<sup>572, 573</sup> but the occurrence is unusual.<sup>571</sup> In practically all of the subjects, neutropenia developed only after at least several weeks of use of one of these drugs, was often heralded by a rash or fever, and the bone marrow showed decreased numbers of myeloid precursors.<sup>570</sup> No case in which the drug was readministered after the patient had recovered from severe neutropenia has come to our attention. The mechanism of the leukopenia may be similar to that seen with the phenothiazines, since phenylhydantoin decreased <sup>3</sup>H-uridine uptake by bone marrow cells obtained from patients recovered from phenylhydantoin leukopenia.<sup>567</sup>

### Antihistamines

These agents rarely cause leukopenia or agranulocytosis. In the few instances reported (Table 41-7), leukopenia and neutropenia appeared only after a period of at least five weeks of drug ingestion.<sup>580</sup>

### Antimicrobial Agents

A wide variety of antimicrobial agents have been reported to cause leukopenia or neutropenia, and, on more rare occasions, agranulocytosis. *Chloramphenicol* appears to be the antibiotic that most commonly affects leukocytes,<sup>457, 461</sup> but it is reported to cause aplastic anemia (Chapter 56) six or seven times as often as neutropenia.<sup>453</sup> Historically the *organic arsenicals* such as arsphenamine<sup>600</sup> and mapharsen<sup>595</sup> used in the treatment of syphilis were among the earliest antimicrobial

agents to cause neutropenia. They, too, caused aplastic anemia more frequently than single cytopenias.<sup>600</sup> The development of neutropenia often was gradual, in most instances appearing after several weeks or more of injections and often heralded by nausea, vomiting, fever, headaches, and other symptoms.<sup>592,595</sup> The incidence ranged from as low as only one or two cases in over 4,000 patients treated with mapharsen<sup>595</sup> to 12 cases of neutropenia in 1,882 patients thus treated. The occurrence of serious reactions leading to death appears to have been rare.

A number of agents, for example, *penicillin*,<sup>605</sup> *methicillin*,<sup>598,601</sup> *ampicillin*,<sup>594</sup> *para-aminosalicylic acid*,<sup>603</sup> *isonicotinic acid hydrazide*,<sup>589</sup> *ristocetin*,<sup>593,602</sup> *nitrofurantoin*,<sup>599</sup> *novobiocin*,<sup>604</sup> and *cephalothin*,<sup>597</sup> have been reported to cause neutropenia in one or two isolated instances. Cephalothin appeared to adhere to neutrophils (but not lymphocytes) from either normal subjects or the patient; the coated cells then presumably reacted with antibody, causing noncomplement-mediated destruction of the "innocent bystander" leukocytes.<sup>597</sup> *Tibione*, an antituberculous drug, caused neutropenia in about 1% of those treated with this drug.<sup>591</sup> *Metronidazole* caused neutropenia in about 2% of patients so treated, but the neutrophil count usually returned to normal even if used of the drug was continued<sup>606</sup> and no profound or dangerous reactions have been reported.<sup>596,606</sup> A few drugs, such as *lincomycin*, to date appear to have been incriminated on the basis of insufficient evidence.<sup>590</sup>

### Miscellaneous Drugs (Table 41-7)

A wide variety of other drugs and chemicals have been reported to occasionally cause neutropenia or agranulocytosis, although, with *phenindione*, the incidence of neutropenia was around 1%.<sup>639</sup> The neutropenia has usually developed after prolonged treatment,<sup>620,623,630,636</sup> and one drug, *procainamide*, that had produced neutropenia was even given again for some time before the neutropenia recurred.<sup>624</sup> An acute, immuno-

logic type of reaction was demonstrated in association with treatment with *mercurial diuretics*.<sup>625</sup>

### Idiopathic Reactions

It has not been possible to incriminate drugs in all cases of neutropenia or agranulocytosis. The proportion in which no etiologic agent was identified was as high as 38%<sup>461</sup> in some of the early experiences, but became much smaller as suspicion of a drug as the etiologic basis increased.<sup>457,460,483</sup> A careful history and repeated questioning of patients and family will often reveal a probable cause.<sup>638</sup>

### Symptomatology

In fulminating agranulocytosis, the onset is sudden and is marked by a chill, high fever, and necrotizing angina. Prostration is extreme. The patient often looks pale, yet the mucous membranes are of normal color or cyanotic. Jaundice is sometimes present. Gangrenous ulceration may be found on the gums, tonsils, soft palate, lips, tongue, pharynx, or buccal mucous membranes, and somewhat less frequently in the skin, nose, vagina, uterus, rectum, or anus. A dirty-yellow, gray or greenish-black membrane covers an underlying ulcer, but the surrounding tissue may show little reaction. Regional adenopathy is present in such subjects, but generalized lymphadenopathy does not occur. Splenomegaly and bone tenderness are very unusual and the liver is rarely enlarged. The fever is high, the pulse rapid and weak, and death ensues in a few days. Plum<sup>460</sup> noted that, with few exceptions, the duration of the illness in fatal cases was three to nine days. Three fourths of his patients died within three days following admission to the hospital.

When it is possible to obtain an adequate history, it is often found that a sensation of fatigue and overpowering weakness has preceded the onset of illness by two or three days. Sore throat may not appear until 12 to

24 hours after the onset of other symptoms.<sup>460</sup> Painful deglutition, headache, rigors, and chilly sensations are common and vomiting, dyspnea, mental confusion, and pain in different parts of the body may occur. Dermatitis or a rash has been observed in about 10% of the subjects.<sup>460</sup>

The train of events in patients with agranulocytosis due to drugs may be divided into three periods: (1) malaise, fever and perhaps a chill, prodromal symptoms that are often forgotten; (2) a period of freedom from symptoms except for fatigue and prostration, during which time the leukocyte count falls and the granulocytes disappear; (3) the final and frequently fatal stage when, resistance being lowered by the absence of granulocytes, infection occurs in those regions normally harboring bacteria and progresses with the extreme rapidity to be expected in defenseless tissues.

In other patients, as already discussed, the course is less rapid and the symptoms not so fulminating. These patients should perhaps not be classed with those presenting the typical Schultz syndrome

### The Blood

In typical agranulocytosis, deficiency in granulocytes is the outstanding finding, but usually other types of leukocytes also are reduced in number. In patients with fulminating cases the leukocyte count is usually less than  $2.0 \times 10^9$  cells/l and frequently it is below  $1.0 \times 10^9$  cells/l. Counts as low as  $0.05 \times 10^9$ /l have been recorded. The granulocytes may be completely absent or 1 to 2% may be found. These cells may possess a pyknotic nucleus and vacuolated cytoplasm with poorly staining granules. Myelocytes are seen only when recovery begins.

The majority of the cells that are to be found are lymphocytes. In some cases, monocytes may be increased relatively and even in absolute numbers. It was suggested that this represents a special type of agranulocytosis (*leukopenic infectious monocytosis*).<sup>378-379</sup> In other instances a number of cells of the Turk "irritation" type have been described.<sup>460</sup>

In chronic neutropenia of slow onset, the leukocyte count is rarely below  $2.0 \times 10^9$  cells/l and the granulocytopenia is less pronounced.

In patients with typical cases there is no anemia or thrombocytopenia and bleeding and coagulation times are normal. In a number of patients a slight or moderate degree of anemia has been observed, but in most of these there was no evidence that this did not exist before the presenting illness. The appearance of the red cells is normal and the number of reticulocytes is normal. The sedimentation rate, however, is greatly accelerated. The icterus index may be moderately raised.

### Bone Marrow

In the classic subject, the bone marrow, examined by biopsy or on postmortem, shows normal erythropoietic tissues and normal numbers of megakaryocytes. The picture as a whole may be one of moderate hypoplasia or of hyperplasia.<sup>461</sup> The striking feature often has been a lack of granulocytes, including polymorphonuclear cells, metamyelocytes, and myelocytes. The observation that promyelocytes and myeloblasts were found in the bone marrow at the time of examination led to the erroneous designation "maturation arrest."<sup>650</sup> Plasma cells, lymphocytes, and reticulum cells may be increased in number.<sup>618</sup>

### Other Laboratory Findings

The urine may contain traces of albumin but is otherwise normal. Blood cultures often have been positive and a great variety of organisms have been found in these as well as in throat cultures.

### Diagnosis

It is most important that the diagnosis be made in the early stage before septicemia has developed. However, the early symptoms are so much like those of many other illnesses that early recognition is unlikely unless the

physician has a high index of suspicion and obtains a leukocyte count whenever he is confronted with symptoms of unexplained weakness and profound exhaustion, or those of a severe acute infection. It is to be remembered that local symptoms in the buccal cavity may not always be present in agranulocytosis.<sup>460</sup> When drugs known to be associated with granulocytopenia are being employed, it is important that the physician be alert for the possible development of this syndrome.

Once the blood has been examined, it should not be difficult to rule out the possibility of the various types of pharyngitis and other infections occurring in the mouth or throat because these generally are accompanied by leukocytosis. Infections such as typhoid fever, measles, rubella, and undulant fever, which are associated with leukopenia, can be readily distinguished from agranulocytosis by their more gradual onset and characteristic symptoms and signs; but influenza is not so easily differentiated. In any of the conditions named it is most unusual for the leukocyte count to reach the low levels noted in agranulocytosis.

Other disorders that may be confused with agranulocytosis include acute "aleukemic" leukemia and aplastic anemia. These are usually accompanied by anemia and thrombocytopenia. The former usually is characterized by the presence of a few immature leukocytes in the blood as well as by adenopathy and splenomegaly. If doubt remains, bone marrow examination should make the diagnosis clear. Like agranulocytosis, infectious mononucleosis is marked by changes that are confined to the leukocytes but extreme leukopenia is unusual; the typical lymphocytes are found and reaction to the heterophil antibody test is positive. Several rare cases of agranulocytosis associated with infectious mononucleosis have been reported.<sup>653</sup>

### Prognosis and Course

Before the sulfonamides and antibiotics became available, the prognosis was very

poor. In Plum's series<sup>460</sup> of 88 patients, the mortality was 84%. In 7%, death occurred after temporary improvement. Statistics by other authors<sup>461</sup> gave the mortality as 70 to 90%. Unfavorable signs are confusion and drowsiness, great prostration, jaundice, necrosis of the skin, a leukocyte count less than  $1.0 \times 10^9$  cells/l with absence of all granulocytes, or the onset of complications such as pneumonia. Mortality is greatest in patients of advanced age.

Death may occur as the result of sepsis, pneumonia, hemorrhage following necrosis, or other causes even after hematologic improvement has set in. Before the importance of drugs as etiologic agents was recognized, relapses were common.

Improvement is heralded by the reappearance of leukocytes of the granular series in the blood. These at first are myelocytes and metamyelocytes. Myeloblasts may be seen. Segmented neutrophils are the last of this series to make their appearance. The presence of monocytes,<sup>461</sup> especially if they persist,<sup>654</sup> has been said to be a good sign. The leukocytic reaction may be very rapid and marked degrees of leukocytosis, even of "leukemoid" character, may be reached, although counts of about  $15.0 \times 10^9$  cells/l have been recorded most often.<sup>461</sup>

With the availability of potent antibiotics to control the complicating infection the outlook, even in severe cases, now is far better than when agranulocytosis was first discovered, provided the potential offending agent is sought out and its further use interdicted.

### Treatment

The most important measure is to discover, if possible, the *offending agent* and to *prohibit its further use*. In this regard it is important to warn patients given drugs that may cause granulocytopenia to discontinue their use immediately if any adverse reaction occurs and to report to the physician without delay. It is of almost equal importance to prevent overwhelming sepsis from developing before the leukocytes reappear. Suitable smears and cultures must be taken immedi-

ately in an effort to identify the organisms causing secondary infection and then a best guess must be made and treatment with the bactericidal drug or drugs most likely to be effective should be initiated. Once the results of culture and sensitivity studies are known, the therapy can be readjusted.

When the granulocytopenia is due to the action of arsenic or gold,<sup>626</sup> BAL (British Anti-Lewisite, 2,3-dimercaptopropanol) may be given intramuscularly, in doses of approximately 150 mg (1.5 ml) of a 10% solution in oil, every four hours for the first two days and then in this dosage twice daily for another eight to ten days. This agent will facilitate excretion of the toxic metal. Oral penicillamine (1 g/day in divided dose) also may be used and has been shown to enhance gold excretion.<sup>649</sup> It may avoid the complication of abscess or infection at injection sites that has occurred with BAL therapy.<sup>626</sup>

The general care of the patient is of great importance. Oral hygiene must receive particular attention in order to prevent the development of painful and serious ulcerations.

No means has been found to effectively stimulate granulocyte formation and, furthermore, it may be questioned whether the hematopoietic system is capable of producing these cells more rapidly than occurs once there is no further exposure to the causative agent.<sup>461</sup> The evidence that pentnucleotide<sup>652</sup> was valuable in the treatment of agranulocytosis was never convincing<sup>460,461,523</sup> and there certainly is no indication for its use now that potent antibiotics are available. Transfusions of blood from patients with leukemia<sup>646</sup> or with leukocytosis resulting from some infection were not found to be of value.<sup>460,652</sup> Injections of leukocytes, "leukocytic cream,"<sup>655</sup> liver extracts,<sup>650</sup> and various vitamins, the feeding of bone marrow, especially yellow marrow<sup>647</sup> and marrow extracts, and the irradiation of the long bones with "stimulating doses" of x rays<sup>651</sup> all had their brief popularity but never earned a place in the management of agranulocytosis. In recent years, considerable effort has been expended to develop methods for collecting fresh neutrophils in large enough numbers to make neutrophil transfusions therapeutically use-

ful. There are several problems.<sup>645</sup> (Chapter 12).

1. The short survival and rapid turnover of blood neutrophils render the effect of such transfusions evanescent at best.

2. Because neutrophils are fragile and easily damaged, collection techniques must involve minimal handling and only brief sojourn outside the body.

3. Large numbers of neutrophils must be given (eg, about  $5 \times 10^{10}$  cells just to replace the normal blood neutrophil pool) and thus the only practical donors are patients with chronic myelocytic leukemia. Such cells can and have been given safely and without transmission of leukemia, but whether they are of real benefit in agranulocytosis remains to be demonstrated.

4. The repeated transfusion of neutrophils may result in sensitization of the recipient. Some work has been done on typing leukocytes for transfusion, but such techniques are usually available only in large medical centers. The chances of finding compatible donors in the general population are remote, but if the patient has many siblings the chances are considerably improved.

In spite of the above difficulties, neutrophil transfusions are being used in some large medical centers to tide patients over periods of granulocytopenia induced by chemotherapy, and there is now some evidence that they are helpful (page 510).

In the classic case of acute agranulocytosis the use of adrenocorticosteroids or ACTH is not justified. The avoidance of continued exposure to a possible offending drug and the control of infections, as they arise, are far more important. In the absence of infection, no therapy is indicated. "Prophylactic" antibiotic administration to patients with chronic neutropenia is both unnecessary and dangerous; such patients may live without trouble for months and even years without infections developing.

## Pathology

In agranulocytosis the most significant feature revealed by autopsy is a lack of granulocytes. Polymorphonuclear leukocytes are

conspicuously absent about the necrotic lesions that may be found in the oral cavity, skin, vagina, uterus, or the gastrointestinal tract, and only plasma cells and lymphocytes are seen. Enormous collections of bacteria are to be found. In the lungs there may be pneumonic lesions with a similar lack of granulocytes, or gangrene. The liver is often enlarged and cloudy swelling, fatty degeneration, or small areas of necrosis may be present. The spleen is frequently somewhat heavier than normal. There is marked engorgement with blood, the lymph follicles are small, granulocytes are absent, and there may be small areas of necrosis. Of the lymph nodes, only those draining infected areas are enlarged. Microscopically they show hyperemia, hemorrhage, and necrosis with some obliteration of the normal structure.

The bone marrow was described on page 1298.

## Leukemoid Blood Pictures

Patients with blood findings that resembled some type of leukemia, but in whom leukemia was not confirmed by the subsequent course of the illness or at autopsy, have been referred to as exhibiting a leukemoid blood picture. More restrictive definitions have been proposed, such as those which require a leukocyte count greater than  $50 \times 10^9$  cells/l or the presence of a certain proportion of blasts in the blood,<sup>681,682</sup> but these have not facilitated classification or understanding since their use excludes some cases that, in fact, simulate leukemia. In some patients, only the magnitude of the leukocytosis or the presence of young forms suggested leukemia<sup>672,689</sup>; in others, the presence of anemia or thrombocytopenia made the differentiation more difficult. In spite of the confusing blood findings the clinical diagnosis has not been difficult in most cases.<sup>672,689,692</sup> In a few the presence of adenopathy, splenomegaly, fever, or hemorrhage made exclusion of leukemia difficult or impossible.<sup>667,709</sup> Not infrequently the true diagnosis was made only at autopsy in such patients,<sup>667</sup> and differentiation was not always possible even then.<sup>686,692,709,715</sup>

**Table 41-8. Diseases Most Commonly Giving Rise to a Leukemoid Blood Picture**

- 1 Infections presenting pictures resembling  
Myelocytic or myeloblastic leukemia pneumonia, diphtheria, tuberculosis  
Lymphocytic leukemia<sup>7</sup> whooping cough, chickenpox, infectious mononucleosis, infectious lymphocytosis, tuberculosis  
Monocytic leukemia tuberculosis
- 2 Intoxications eclampsia, severe burns, mercury poisoning
- 3 Malignant disease, especially with bone metastases also multiple myeloma, myelofibrosis, Hodgkin's disease
- 4 Severe hemorrhage, sudden hemolysis of blood

Leukemoid reactions occur in association with a variety of infections, intoxications, malignant diseases, and even severe hemorrhage or sudden hemolysis (Table 41-8). Bone marrow aspiration and biopsy, and liver and lymph node biopsy, together with careful examination of these materials by culture and special stains, should be helpful in differential diagnosis.<sup>684</sup> It is apparent that unusually high leukocyte counts or immature cells in the blood must be the consequence of abnormalities in production or release of cells, possibly coupled with defective removal and destruction. However, little is known about the mechanisms that control these events even in the normal state (page 253).

*Myeloid leukemoid blood pictures* may be considered under several headings:

1. Exceptionally high leukocyte counts (mainly neutrophils) with little immaturity and few if any other features to suggest leukemia. Such findings have been encountered in Hodgkin's disease ( $54.4 \times 10^9$  cells/l),<sup>681</sup> non-metastatic gastric carcinoma with infection ( $110.0$ ),<sup>700</sup> acute infection with hemorrhage in advanced breast carcinoma ( $120.0$ ),<sup>692</sup> carcinoma of the lung ( $93.0$ ),<sup>672,714</sup> adrenal carcinoma with metastases ( $88.0$ ),<sup>683</sup> retroperitoneal fibrosarcoma ( $82.0$ , personal observation), alcoholic fatty liver ( $38.9$ ),<sup>666</sup> acute glomerulonephritis ( $51.9$ ),<sup>682</sup> dermatitis herpetiformis ( $68.0$ ),<sup>671</sup> and acute rheumatoid arthritis ( $86.0$ ).<sup>664</sup> Such

patients seldom if ever present any serious difficulty in clinical diagnosis.

2. Leukocytosis of variable degree with a considerable left shift in the differential count including myelocytes, promyelocytes, and a few blasts, thus producing a blood picture similar to that of chronic myelocytic leukemia (CML). This has been reported in association with a variety of tumors, many with metastases to bone.<sup>693,694</sup> In most of these patients the leukocyte count was normal or only moderately increased ( $<17.0 \times 10^9$  cells/l), and myeloid immaturity increased with increasing anemia and bone involvement.<sup>699</sup> Disseminated tuberculosis also has produced a picture that resembled CML with counts as high as  $220.0 \times 10^9$ /l,<sup>697,694,707</sup> as have a variety of other infections including staphylococcal pneumonia (114.0), meningococcal and hemophilus meningitis, salmonella and paracolon sepsis, pneumococcal endocarditis (76.8), diphtheria (70.0), bubonic plague (100.0),<sup>692</sup> and infected abortion (112.0),<sup>692</sup> as well as lymphoma,<sup>691</sup> eclampsia,<sup>696</sup> rheumatoid arthritis,<sup>693</sup> and heavy metal (Hg) or drug toxicity.<sup>670,681</sup> The use of ancillary diagnostic aids such as the leukocyte alkaline phosphatase stain, serum vitamin B<sub>12</sub> level, and karyotype analysis for the Ph<sub>1</sub> chromosome would be expected to be helpful in those few cases in which real difficulty in differentiation from CML exists,<sup>694</sup> but confusing results have sometimes been obtained.<sup>684,714</sup> Myelofibrosis and osteosclerosis frequently produce a blood picture that may simulate CML, but the red cell changes often suggest the diagnosis and marrow biopsy provides confirmation (page 1779).

3. A leukemoid picture simulating acute myeloblastic leukemia has been associated with disseminated tuberculosis or tuberculosis involving the spleen and lymph glands,<sup>693,697,707,708,709,712</sup> and has been observed when the bone marrow was regenerating in patients with agranulocytosis and superimposed infection, whether bacterial<sup>692,695</sup> or protozoan.<sup>687,702</sup> A picture simulating aleukemic, myeloblastic leukemia has been described in alcoholics with infec-

tion. There was neutropenia and a mild shift to the left in the blood, and the bone marrow revealed few neutrophilic precursors more mature than promyelocytes.<sup>699</sup> The leukopenia lasted only several days after hospitalization and a resurgence of granulocytopoiesis with band and segmented forms was evident in the marrow by four days. In these alcoholics the blood leukocyte count failed to rise following injection of endotoxin,<sup>699</sup> thus indicating decreased marrow granulocyte reserves.<sup>699</sup> Several similar cases have been described in association with megaloblastic anemia of the puerperium<sup>704</sup> and we have seen such a reaction in a patient with pernicious anemia. Such AML-like reactions suggest that, with poor marrow granulocyte reserves for whatever reason (drug suppression, folate or B<sub>12</sub> deficiency, alcoholism, etc.), a severe infection exhausts the marrow stores and leukopenia with a variable degree of shift to the left develops. As restoration of myelopoiesis begins the appearance of the marrow is not unlike that of myeloblastic or promyelocytic leukemia.<sup>687,695</sup> The best approach in such cases is to treat any infection aggressively with bactericidal antibiotics after obtaining appropriate cultures, to supply vitamin B<sub>12</sub> and folate parenterally if the patient may be nutritionally deficient, and to avoid anti-leukemic therapy until it is clear that one is not dealing with a leukemoid reaction.

The presence of Auer rods has been reported in patients with AML-like leukemoid reactions associated with disseminated tuberculosis.<sup>709</sup> In these patients, even though no evidence of leukemia was found at autopsy, tuberculosis and acute leukemia may have coexisted since, it is claimed, tuberculosis may so modify the morphologic features of leukemia that the characteristic leukemic infiltrations are not demonstrable.<sup>684</sup>

Lymphoid leukemoid reactions also may be of several types:

1. A high lymphocyte count consisting mostly of mature lymphocytes, thus simulating chronic lymphocytic leukemia (CLL), has been most commonly found in infants

and young children with *pertussis*. Leukocyte counts as high as  $272 \times 10^9$  cells/l have been reported. The prognosis in such cases was regarded as serious,<sup>660,710</sup> particularly in the pre-antibiotic era.<sup>680,711</sup> Differentiation from CLL is easily made on the basis of the youth of the patients and the lack of adenopathy and splenomegaly. *Infectious lymphocytosis* also results in a high lymphocyte count (page 1289). The young age of the patient and the presence of fever, as well as the frequent involvement of several family members, are helpful differential features. A CLL-like blood picture has been associated with other diseases as well, eg, dermatitis herpetiformis,<sup>671</sup> exfoliative dermatitis,<sup>675</sup> chickenpox,<sup>679</sup> cancer of the stomach,<sup>663</sup> metastatic melanoma,<sup>691</sup> breast cancer,<sup>690,703</sup> and miliary tuberculosis.<sup>677</sup> The simultaneous presence of CLL or non-Hodgkin's lymphoma and one of these diseases cannot be ruled out in some of these cases since the patients were not always observed for long periods and some received x-ray therapy.

2. When numerous young mononuclear cells have been present in the blood, whether the leukocyte count was low, normal, or increased, *acute lymphoblastic leukemia* (ALL) has been simulated. The most common disorder leading to confusion with ALL is infectious mononucleosis (Chapter 43). Although leukocytosis greater than  $30.0 \times 10^9$  cells/l occurs in less than 1.5% of patients,<sup>662</sup> counts up to  $80.0 \times 10^9$  cells/l have been reported.<sup>674,703</sup> and we have seen one patient with  $100.0 \times 10^9$  cells/l. A similarly confusing picture has been reported in infectious hepatitis, in the post-transfusion syndrome, and in some cases of drug sensitivity,<sup>713</sup> as well as in association with mumps,<sup>676</sup> congenital syphilis,<sup>668</sup> tuberculosis,<sup>696,709</sup> and a variety of other illnesses. It should be noted that young-appearing, DNA-synthesizing cells may enter the blood in response to both inflammation and antigenic stimulation. Some of these cells may be lymphocytes while others may belong to the monocytic series.<sup>371</sup>

*Other varieties of leukemoid reaction have*

been reported, but they are very rare. Only one case of *monocytic leukemoid* reaction has been reported and this was associated with tuberculosis of the lymph glands, lungs, liver, and ileum and a mediastinal teratoma. The leukocyte count reached  $82 \times 10^9$  cells/l with 42% monocytes. This patient died five months after becoming ill and it is difficult to rule out the possibility of the concurrence of leukemia.<sup>678</sup>

*Eosinophilic leukemoid* reactions with high concentration of eosinophils in the blood have been reported in association with amebiasis<sup>688</sup> and melanomatosis<sup>701</sup> as well as in cases which simulated (and may have been) chronic eosinophilic leukemia<sup>698</sup> (page 1285).

### Experimental Production of Leukemoid Reactions

The administration of tuberculin to previously sensitized rabbits has elicited a leukemoid reaction with leukocyte concentrations reaching  $124 \times 10^9$  cells/l. The reaction was predominantly granulocytic with considerable shift to the left<sup>673</sup>; monocytic response was minimal. Leukemoid reactions with white cell counts (chiefly neutrophils) of several hundred thousand have been reported in mice harboring several types of transplantable tumor.<sup>661,669</sup> Resection of the tumor reduced the leukocyte count and if the tumors recurred so did the leukocytosis. A substance that appears to stimulate granulocyte production and release was isolated from one such tumor<sup>669</sup> (page 253). It has been suggested that the presence (and presumably overgrowth) of leukovirus in animals with weakened body defenses may result in leukemoid reactions.<sup>701</sup>

The *lymphocytic leukemoid* reaction produced by pertussis has been studied in mice. It appears that pertussis organisms liberate a substance that attaches to lymphocytes and prevents their "homing" to lymphoid organs; lymphocytosis develops due to decreased egress of lymphocytes from the blood.<sup>706</sup>

## *Quantitative, Morphologic, and Functional Disorders of the Granulocyte and Monocyte-Macrophage Systems*

**Quantitative Disorders of Granulocytes**  
**Disorders of Phagocytic Leukocytes Characterized by Morphologic Changes**  
**Functional Disorders of Leukocytes Not Characterized by Morphologic Changes**  
**Disorders Involving the Monocyte-Macrophage System—The "Storage Diseases"**  
**Histiocytosis X**

**I**N Chapter 41, variations in the numbers and morphologic characteristics of leukocytes occurring in association with disease or exposure to drugs were described and their significance was discussed. To be considered in the present chapter are alterations in the granulocyte and monocyte-macrophage systems that mainly represent (1) abnormalities in production, destruction, or control mechanisms that result in leukopenia (neutropenia) or neutrophilia; (2) abnormalities of the cells of these systems that produce detectable morphologic changes and may or may not affect the cells' function; (3) enzymatic deficiencies that result in the accumulation of incompletely digested metabolic products (the "storage diseases"); or (4) other disorders characterized by functional abnormalities not associated with prominent morphologic changes, such as those leading to chronic granulomatous disease of childhood.

Many of these conditions are rare, even extremely rare. A number are inherited, not infrequently arising out of consanguineous marriages. A few are acquired. Study of some of these conditions, such as chronic granulomatous disease, Chediak-Higashi syndrome, myeloperoxidase deficiency, and the storage diseases, has provided considerable information about the normal function of leukocytes and macrophages.

### **Quantitative Disorders of Granulocytes**

From time to time, cases of neutropenia do not fit well into the recognized categories discussed in Chapter 41. Certain special features seem to distinguish them from one another, and one feature is common to them all—they are very poorly understood. They illustrate how fragmentary is our knowledge of the factors governing the numbers of leukocytes that are produced, circulate in the blood, and are destroyed.

Classification of these neutropenias on the basis of mode of inheritance or kinetic mechanisms has been largely thwarted by lack of adequate information. The result is a "pot-pourri" of clinical syndromes.

### Infantile Genetic Agranulocytosis<sup>9</sup>

Infantile genetic agranulocytosis is inherited as an autosomal recessive trait and is characterized by severe neutropenia ("almost complete agranulocytosis"); it is accompanied by frequent infections of various kinds, most commonly furuncles and carbuncles. The outcome usually is death within the first year of life. In the first study reported, consanguinity of the parents was established in five of nine families.<sup>9</sup> Symptoms may begin as early as one to three weeks after birth. Although infections may clear up with intensive antibiotic treatment, they soon recur. The neutropenia is severe, fewer than  $0.5 \times 10^9$  neutrophils/l usually being found. Total leukocyte counts often give values within the normal range and monocytosis is prominent in some subjects. Platelet concentration is normal, but moderate anemia is the rule. Examination of the bone marrow reveals variable cellularity (normal,<sup>15</sup> increased,<sup>5</sup> or decreased<sup>9</sup>); or few or no neutrophils, more mature than myelocytes, are present and yet mature eosinophils and basophils are found.<sup>15</sup> Vacuoles and atypical nuclear shapes are prominent in the promyelocytes and myelocytes, and atypical erythroid forms also have been noted.<sup>9</sup> Electron microscopy did not establish the nature of the vacuoles.<sup>5</sup> Culture of marrow cells from one patient resulted in increased maturation when normal serum or cysteine was added to the medium. Thus it was suggested that the basic defect may be inability to utilize sulfur-containing amino acids,<sup>9</sup> but administration of this amino acid produced no clinical improvement. Other studies of marrow particles cultured *in vitro* showed no or very slow maturation of neutrophils.<sup>15</sup> Patients' marrow cells dispersed in agar plates exhibited normal growth in some studies<sup>3</sup> and abnormal growth in others.<sup>11a</sup> Chromosome analyses have revealed no abnormality in most cases studied.<sup>7</sup> Normal neutrophils transfused into affected patients left the blood at approximately normal rates, thus suggesting that the defect is in cell production rather than due to increased cell destruction. The infusion of

normal plasma did not alleviate the neutropenia or alter the appearance of the bone marrow.<sup>15</sup>

Sporadic cases thought to represent the same disorder have been reported.<sup>1,2,7,10,11,12,13,15</sup> Hyperglobulinemia was noted in many of the subjects.<sup>7,11,12,15</sup> Some of the reported patients have survived into the late teens,<sup>7,12,15</sup> apparently because monocyte function is preserved and compensates for the missing neutrophils.<sup>15</sup> Treatment with steroids,<sup>7,15</sup> testosterone,<sup>11</sup> and/or splenectomy<sup>7</sup> has not been helpful.<sup>7,15</sup> One patient developed acute leukemia at age 13.<sup>7</sup>

### Familial Neutropenia Caused by Deficiency of a Plasma Factor<sup>20,22</sup>

Two brothers, ages 13 and 10, born to healthy and unrelated parents who had two healthy daughters, were noted to suffer from periodontal disease and frequent infections of the throat. Neutropenia with a shift to the left was found and the bone marrow showed "maturation arrest" at the myelocyte level and prominent eosinophils. Erythropoiesis was also thought to be abnormal. This picture is similar to that of infantile genetic agranulocytosis except for the longer survival and occasional transient rises in total leukocyte and granulocyte concentrations in association with infections. The plasma from the two boys inhibited differentiation of normal marrow cells *in vitro*. In addition, transfusion of normal serum led to short-term normalization of myelopoiesis in one boy, while in the other the effect was equivocal.

### Granulocytopenia with Associated Immunoglobulin Abnormality<sup>29</sup>

#### Familial Form

Three young brothers died at ages 3, 27, and 41 months, respectively, from a disease characterized by ulcerative stomatitis and pharyngitis, repeated respiratory infections, neutropenia, lymphadenopathy, splenomegaly, and hypogammaglobulinemia. The fact that their two sisters remained healthy

suggests that X-linked recessive inheritance was the basis for their disease. Their bone marrow showed arrested maturation at the myelocyte level, the majority of the granulocytes being promyelocytes and myelocytes. However, a few metamyelocytes were present and occasionally complete, temporary recovery of the blood and marrow neutrophil levels took place. A search was made for antibodies of several varieties but none was found. Skin window studies revealed a delayed and hypocellular response and, according to the few details reported, the phagocytic ability of the patients' leukocytes appeared to be reduced. At necropsy, extensive focal organizing pneumonitis was present without evidence of granuloma formation. No organisms were identified. The inflammatory response was minimal although in one of the boys small abscesses composed of young neutrophils were seen. The lymph nodes and thymus were relatively normal.

### **Nonfamilial Form**

This category includes six of eight patients with agammaglobulinemia who exhibited neutropenia and an associated shift to the left in the marrow neutrophil picture.<sup>26</sup> The neutropenia was transient in three of them, chronic in two, and appeared to be cyclic in one. Another patient with decreased 7S gammaglobulins and increased 19S globulins exhibited intermittent neutropenia that seemed to disappear as long as he was given gamma globulin injections monthly.<sup>25</sup> A similar patient with absent  $\beta$ -2A globulin and increased  $\beta$ -2 macroglobulin was studied with  $^{32}\text{P}$ -labeled neutrophil infusions; the  $t_{1/2}$  was four hours and a combination of increased cell destruction and inadequate marrow compensation was suggested.<sup>27</sup> Several bone marrow examinations revealed almost no plasma cells.

### **Congenital Aleukia or Reticular Dysgenesis<sup>35</sup>**

This very rare disorder was reported in newborn twin brothers who had no blood

leukocytes of any kind; the erythroid and megakaryocytic systems were normal. No antibodies against leukocytes were found in either the mother or the boys. In both boys, at necropsy virologic studies of body fluids and tissues revealed no abnormality; lymph nodes, tonsils, and Peyer's patches were absent and there were no lymphocytes, plasma cells, or follicles in the spleen. The bone marrow showed normal erythroid development and megakaryocytes, but no myeloid cells of any stage could be identified. It appears that congenital aleukia reflects lack of development of the leukocyte systems at the most primitive level and of the most complete degree.

### **Familial Benign Chronic Neutropenia<sup>41</sup>**

Familial benign chronic neutropenia is a rare, relatively benign anomaly that is transmitted as a non-sex-linked dominant trait and is characterized by normal or somewhat low total leukocyte counts, consistent neutropenia, and, usually, relative monocytosis and lymphocytosis, sometimes with eosinophilia. The red cell and platelet systems apparently are normal. The bone marrow is normally cellular, but few myeloid cells more mature than myelocytes are seen.<sup>40,41,44</sup> Clinically the disorder usually is detected by chance. In some affected family members, periodontal disease, a tendency to develop frequent furuncles, and limited neutrophil response to infection have been noted, but in others there appear to be no deleterious effects or symptoms.<sup>41</sup> Dominant transmission, the milder clinical course, and lack of involvement of the erythroid system distinguish this disorder from infantile genetic agranulocytosis.

Neutropenia occurring in family members has been reported under the title "familial benign chronic neutropenia" and may have been the same process as that described in the preceding paragraph. However, the manifestations differed in various ways; eg, there was no shift to the left in the bone marrow and the entity was confined to Yemnicite Jews.<sup>43</sup>

### Transitory Congenital Neutropenia Due to Transplacental Transmission of Neutropenic Factor (Isoimmune Neonatal Neutropenia)

This neutropenia was reported in two infants born of neutropenic mothers.<sup>63</sup> Both infants recovered spontaneously in several weeks. In the mother of one of these children a neutropenic factor could be detected in the serum by leukoagglutination tests or by the production of neutropenia in a normal recipient given the mother's plasma. The factor was associated with the gamma globulin fraction and caused "maturation arrest" in the bone marrow of the normal recipient.<sup>63</sup> In the other child whose mother was neutropenic, the only evidence for a neutropenic factor was the presence of a transitory neutropenia. The reason for the development of these "immune" factors is not clear since no associated disease could be identified. However, fetal leukocytes have been found in maternal blood, especially during the first trimester and after delivery.<sup>64</sup> Furthermore, the congenital neutropenia appeared in the first child of a mother who previously had had no blood transfusions.<sup>63</sup> One case was reported in an infant born to a pancytopenic mother who had lupus.<sup>62</sup>

Under titles similar to the above a number of infants with neutropenia have been described,<sup>53, 56, 59</sup> but the mothers of these infants were not neutropenic and the infants were the products of second or later pregnancies. Frequently, several siblings were affected. It was proposed that maternal isoimmunization might explain this form of neutropenia just as has been demonstrated in erythroblastosis<sup>55, 56, 59</sup>; subsequent studies have provided good evidence for this, at least in some instances.<sup>51, 57</sup> Several antigens (NA1 and NB1) peculiar only to the neutrophil have now been reported and apparently explain the occurrence in several families of neonatal neutropenia that resulted from fetomaternal incompatibility.<sup>57</sup> However, the incidence of neonatal neutropenia secondary to transplacental passage of leukocyte agglutinins must be low since in two series of infants (39<sup>50</sup> and 44,<sup>60</sup> respectively) in whose

mothers leukoagglutinins were found, no instances of neonatal neutropenia were detected. This entity is now referred to as *isoimmune neonatal neutropenia*.<sup>57</sup>

### Chronic Granulocytopenia of Childhood<sup>65</sup>

Chronic granulocytopenia of childhood is a relatively benign, apparently nonfamilial disorder characterized by repeated pyogenic infections beginning soon after birth. In at least some of these patients, complete recovery eventually takes place. Leukocyte concentration is usually normal, but neutrophil counts have ranged from 0 to  $2.0 \times 10^9/l$ ; monocytosis is common. Bone marrow study has revealed normal or moderately increased cellularity with some increase in lymphocytes; neutrophilic bands and metamyelocytes have been plentiful, but mature segmented forms have been absent. In contrast to patients with infantile genetic agranulocytosis, the blood neutrophils of children with chronic granulocytopenia increase in response to infection or to pyrogen or epinephrine injection. The marrow mitotic index is increased and marrow specimens grown in culture exhibit maturation of band forms into segmented neutrophils. For these reasons this disorder has been thought to be due to increased destruction of neutrophils. However, no kinetic studies have been reported. Attempts to detect leukoagglutinins have yielded negative results. Skin window studies showed delayed appearance of cells during the first seven hours.

The main differences between these patients and children with infantile genetic agranulocytosis are: in the former, a milder clinical course, less severe neutropenia, the ability to mobilize some neutrophils, and the presence of myeloid cells through to band forms in the marrow.

### Periodic or Cyclic Neutropenia<sup>65</sup>

The cyclic recurrence of malaise, fever, mild infection (often stomatitis with oral ulcers), and cervical lymphadenopathy has been recorded since 1910. The association of

these symptoms with neutropenia is well established.<sup>86,87</sup> In the majority of patients with this rare disorder, symptoms have begun in infancy, thus suggesting a congenital origin; in a few, the symptoms have begun later, even in the sixth and seventh decades of life. Cases of cyclic neutropenia affecting several family members have been reported.<sup>71,79,83,90</sup> Episodes recur at approximately three-week intervals (12 to 35 days, average 21 days) and symptomatic periods may last from three or four to ten days. During the symptomatic period the blood neutrophil concentration is markedly reduced and lymphocytosis, monocytosis, and/or eosinophilia has been noted in some patients.<sup>85,87</sup> The total leukocyte count may fluctuate with the neutrophil changes or may remain more or less constant in the low normal range.<sup>85,90</sup> Thrombocytopenia has been reported in a few cases.<sup>86</sup> Between attacks, the symptoms disappear completely and the neutrophil count returns to nearly normal levels. However, in most of the subjects the proportion of segmented neutrophils remains less than 50% and sometimes it is less than 20%.

Studies of the marrow at several points in the cycle have demonstrated that granulocyte precursors disappear prior to the onset of neutropenia and reappear before neutrophils reappear in the blood.<sup>81,85</sup> This led most observers to regard the clinical picture as secondary to a periodic failure of neutrophil production.<sup>85,86</sup> This hypothesis has been further supported by (1) failure to find leukoagglutinins in the serum; (2) inability to inhibit *in vitro* neutrophil migration or phagocytic capacity by relapse phase serum; or (3) failure to produce neutropenia or clinical manifestations in persons transfused with patient's serum.<sup>85</sup> Tritiated thymidine and  $DF^{32}P$  kinetic studies have provided more firm evidence against increased neutrophil destruction in the periphery and in favor of a periodic failure or inhibition of neutrophil production in the marrow.<sup>77,81</sup> No relationship to hormone levels or to the menstrual cycle has been established.<sup>85</sup>

The existence in gray collie dogs of a similar syndrome, except that the average cycle runs 8 to 12 days, has made more extensive

pathogenetic study possible.<sup>75,80,88</sup> In these animals, cyclic neutropenia is inherited as an autosomal recessive disorder.<sup>80</sup> Detailed studies of the blood revealed a cyclic pattern of blood neutrophils, eosinophils, monocytes, reticulocytes, and platelets with a wave of myelopoiesis in the marrow preceding the reappearance of neutrophils in the blood.<sup>75,80</sup> These studies, together with demonstrated reduction in marrow reserves before the development of neutropenia and normal  $DF^{32}P$  neutrophil half-disappearance time during the neutropenic phase, all indicate that the condition results from a recurring failure of myelopoiesis at a primitive cell level.<sup>75</sup> Demonstration of cyclic fluctuation of a urinary factor that stimulates myeloid colony growth in culture plates *in vitro* (CSA, see page 254, Chapter 6) may provide further support for this hypothesis.<sup>74</sup> Transplantation of normal marrow cells to a gray collie dog resulted in normal granulocytopoiesis, thus demonstrating that this disorder reflects a genetic stem cell defect.<sup>76</sup>

The course of the disorder in affected individuals (either man or dog) is marked by recurrent infections with periods of well-being interspersed. Treatment with antibiotics may decrease the severity of bacterial infections and reduce the likelihood of dissemination and death. Splenectomy, although not eliminating the cycling, has been reported to result in fewer symptoms in older patients and in those with splenomegaly. In addition, treatment with adrenal corticosteroids and androgenic hormones has at times been reported to be of some benefit.<sup>70,72</sup>

### Chronic Idiopathic Neutropenia

Chronic idiopathic neutropenia is a clinically benign, chronic syndrome that has persisted in those afflicted for 1 to 19 years and is associated with little or no increase in infections, although gingivitis is prominent in some subjects. It is characterized by severe neutropenia ( $0$  to  $0.8 \times 10^9$  cells/l) and a cellular marrow with normal myeloid maturation but lacking segmented neutrophils. Splenomegaly has not been found. Adrenal corticosteroids have not produced an

Fig. 42-1. Marrow specimen from a patient with "myelokathexis." Note the pyknotic nuclei, cytoplasmic vacuoles, and hypersegmented neutrophils with long thin, intrasegmental chromatin strands (From Krill et al.<sup>115</sup> courtesy of the authors and the New England Journal of Medicine.)

increase in neutrophil count nor did splenectomy change the course in one patient so treated.<sup>95</sup> Leukoagglutinins were absent in 13 of 15 patients; the remaining two patients were multiparous women. No treatment appears to be needed for these patients.

### Chronic Idiopathic Immunoneutropenia in Adults

Descriptions have been published of a number of cases of chronic neutropenia in which factors capable of agglutinating normal leukocytes *in vitro* were present in the patients' blood plasma.<sup>100, 101, 102, 103, 105, 106, 107, 108</sup>

In a few instances the patient's plasma was given to a normal recipient whose leukocyte and granulocyte counts dropped as a result.<sup>101</sup> In some of the patients, elevated levels of immunoglobulins of various types that were thought to be of pathogenic significance have been described.<sup>102, 103, 105, 106</sup> The bone marrow picture usually was a cellular one with a variable paucity of the more mature neutrophil forms, thus suggesting "maturation arrest" at the myelocyte stage.<sup>101</sup>

### "Myelokathexis" or Chronic Idiopathic Granulocytopenia

One case of chronic idiopathic granulocytopenia, apparently resulting from intramedullary retention and death of neutrophils,

has been reported.<sup>115, 116</sup> The patient was a 10 year old girl who had suffered from repeated infections and persistent neutropenia since infancy. Numerous bone marrow examinations revealed no "maturation arrest" and segmented neutrophils were present in abundance. However, pyknotic nuclei, cytoplasmic vacuoles, and hypersegmentation with longer than normal chromatin strands separating nuclear lobes were noted (Fig. 42-1). According to DF<sup>32</sup>P kinetic studies, the  $t_{1/2}$  of this patient's neutrophils was shortened in her own circulation and in the circulation of a normal recipient, while normal cells survived about normally in the patient's circulation.<sup>115</sup> Although cells were released from the marrow into the blood after stimulation with endotoxin or in response to infection, the patient's polymorphonuclear neutrophils exhibited decreased motility, decreased phagocytic capacity, and increased permeability to dyes. All of these findings seem to support the hypothesis that the mature granulocytes were functionally and morphologically inferior, that many were retained and died in the marrow, and that the neutropenia and clinical picture were the consequence of this defect.

### The Lazy Leukocyte Syndrome

Two unrelated children (a girl 4½ years and a boy 2½ years of age) who suffered from

recurrent stomatitis, gingivitis, and other infections associated with severe neutropenia but with cellular marrows containing normal numbers of mature neutrophils have been described.<sup>120</sup> Relatively few cells were released into the blood following endotoxin injection, but neutrophil morphology, random mobility, and phagocytic capacity were normal. Opsonin activity and complement-mediated chemotaxis were generated normally by the patients' plasma, but their neutrophils showed deficient response to their own chemotactic factor as well as to that generated in control sera. In another case, neutrophilia and poor cell-spreading on glass with narrow pseudopods, as well as ultrastructural and biochemical abnormalities, suggest a defect in actin filaments.<sup>119</sup> Still other examples of disorders of chemotaxis are being described.<sup>121,123</sup>

### Chronic Hypoplastic Neutropenia<sup>127</sup>

This syndrome is characterized by chronic neutropenia and absolute granulocyte counts often below  $0.7 \times 10^9/l$ , but occasionally rising above 1.8, into the normal range. The total leukocyte count usually is normal and lymphocytosis and/or monocytosis is present. At times, slight anemia or thrombocytopenia has been noted. These patients suffer from repeated infections that are slow to heal, the skin and oral cavity being most frequently affected. Splenomegaly of slight to moderate degree was present in the four patients reported,<sup>127</sup> but the lack of response to splenectomy was thought to exclude the possibility of "primary splenic neutropenia" (see below). Other than neutropenia the outstanding feature was a *remarkable hypoplasia of the entire granulocytic series* in the marrow with relatively undisturbed erythropoiesis and thrombocytopoiesis. No signs of inflammatory, malignant, or other disease that might produce this picture could be found. In one patient the process continued for 25 years. Treatment with immunosuppressive agents has not been helpful.<sup>125</sup>

### Primary Splenic Neutropenia

Primary splenic neutropenia is characterized by neutropenia of variable but often

mild degree ( $1.0$  to  $2.0 \times 10^9$  cells/l), splenomegaly, and myeloid hyperplasia of the marrow; it was said to be cured by splenectomy.<sup>132</sup> The spleen is described as showing extensive reticular hyperplasia, and phagocytosis of blood cells by reticulum cells may be noted. Some degree of anemia or thrombocytopenia may be associated, and in some subjects pancytopenia may occur ("splenic pancytopenia").<sup>130</sup> The relationship between this syndrome and cytopenias associated with Felty's syndrome, Banti's syndrome, and tropical splenomegaly is not at all clear.<sup>130,132</sup>

### Hereditary Neutrophilia

A mother and three of her four children have had life-long, persistent neutrophilia ( $9$  to  $62$  neutrophils  $\times 10^9/l$ ), high leukocyte alkaline phosphatase scores and vitamin  $B_{12}$  levels, hepatosplenomegaly, and Gaucher-like cells in the spleen and marrow, but morphologically and functionally normal neutrophils.<sup>135</sup> An autosomal dominant disorder is postulated.

## Disorders of Phagocytic Leukocytes Characterized by Morphologic Changes

For the most part the disorders to be considered here are rare, usually familial, and often reflect a general metabolic defect whose major manifestation may be more serious in tissues other than in leukocytes. Nevertheless, the leukocytic morphologic abnormalities may come to the attention of the hematologist and familiarity with them and the associated diseases may facilitate diagnosis.

### Pelger-Huët Anomaly

This benign anomaly of leukocytes is inherited as a non-sex-linked, dominant trait. It is characterized by distinctive shapes of the nucleus of leukocytes, by a reduced number of nuclear segments, best seen in the neutrophils, and by coarseness of the nuclear chromatin of the neutrophils, lymphocytes, and

Fig. 42-2 The morphologic changes of Pelger-Huët cells as compared to normal leukocytes. A, Normal neutrophils. B and C neutrophils with bilobed or "pince-nez" nuclei. D, normal myelocyte to contrast with E and F mature Pelger-Huët neutrophils with round or indented nuclei. G, normal eosinophils. H and I mature eosinophils with round nuclei (From Skendzel and Hoffman,<sup>157</sup> courtesy of the authors and Williams & Wilkins Company)

monocytes. Rod-like, dumbbell, peanut-shaped, and spectacle-like ("pince-nez") nuclei with smooth, round, or oval individual lobes (Fig. 42-2, B and C) contrast with the irregular lobes seen in normal neutrophils (Fig. 42-2, A). The incidence of this disorder ranges from as high as 1 in 1000 per-

sons<sup>141,149</sup> to one in 4000<sup>146,157</sup> or 6000,<sup>144</sup> or even one in 10,000.<sup>153</sup> Originally observed mainly in Holland, Germany, and Switzerland, the anomaly has now been described in other parts of the world and in Orientals<sup>160</sup> and Negroes as well as in Caucasians. The practical importance of identifying the Pel-

†Modified from Davidson<sup>144</sup>

ger-Huët anomaly lies in distinguishing this defect from the "shift to the left" that occurs in infection.

The discovery of this anomaly in rabbits led to breeding experiments and the production of homozygotes.<sup>141,157</sup> These studies demonstrated that, in the heterozygote, bilobed, rod-shaped and spectacle forms predominate while, in the homozygote, round nuclei with no evidence of segmentation are predominant. In rabbits the homozygous form was often lethal with most animals dying in utero; the survivors not infrequently suffered skeletal malformations.

Two human homozygotes have been reported.<sup>141,159</sup> In them the cytoplasm of the neutrophils appeared mature, but the nuclei were round or oval in all the neutrophils, in contrast to the fewer than 40% single-lobed neutrophils present in heterozygotes (Table 42-1).<sup>141,144,159</sup> In the homozygotes the eosinophils, basophils, and megakaryocytes also showed dense nuclear chromatin and rounded nuclear lobes; the nuclear lobes were fewer in number than in normal subjects.<sup>141</sup> Examination of the bone marrow revealed normal morphologic features in myeloid precursors through to the myelocyte stage, while electron microscopy revealed persistence of nucleoli in the otherwise mature neutrophils that contained single oval nuclei.<sup>159</sup> This was interpreted as indicating some retardation of nuclear maturation since no cytochemical defects were noted in the cytoplasm.

Pelger-Huët cells appear to be normal functionally,<sup>159</sup> are able to phagocytize mi-

croorganisms,<sup>157</sup> and survive normally in the circulation in both man<sup>154</sup> and the dog.<sup>142</sup>

The Pelger-Huët heterozygote is recognized by finding: (1) 69 to 93% of the neutrophils to be of the bilobed, "pince-nez" type; (2) very few cells with three lobes (usually fewer than 10%); and (3) rare or no cells with four lobes (Table 42-1).<sup>144,146,157</sup> This is in contrast to the findings in normal blood smears in which no more than 27% of the cells are bilobed and significant numbers of cells have three or more lobes (Table 42-1).<sup>157</sup> The presence of similar abnormalities in the blood smear in other family members also is helpful in establishing the diagnosis. In heterozygotes, mature neutrophils with round or oval nuclei of the type that is characteristic of the homozygous state may increase after stresses such as the injection of colchicine<sup>148</sup> or pyripher.<sup>149</sup> A shift towards increased numbers of neutrophil lobes was described in a patient with the anomaly who developed pernicious anemia.<sup>140</sup>

#### Pseudo- or Acquired Pelger-Huët Anomaly

Cells with morphologic changes like those described above have been noted occasionally in association with myxedema, acute enteritis, agranulocytosis, multiple myeloma, malaria, leukemoid reactions secondary to metastases to the bone marrow,<sup>155</sup> drug sensitivity,<sup>150</sup> or chronic lymphocytic leukemia.<sup>149</sup> More commonly, pseudo-Pelger-Huët cells (Plate XVI, C, D, page 1322) are seen in patients with

myeloid leukemia of either the acute or chronic type or in those with myeloid metaplasia.<sup>145,156</sup> In these subjects the pseudo-Pelger-Huet cells tend to appear late in the disease, often, but not always, after considerable chemotherapy has been administered. In addition, the majority of the nuclei are of the single oval type characteristic of the homozygous state.<sup>145</sup>

### Alder-Reilly Anomaly

This anomaly, inherited as a recessive trait,<sup>165</sup> apparently does not interfere with leukocyte function.<sup>173</sup> It is characterized by the presence of larger than normal azurophilic, and basophils ("Alder-Reilly bodies"), which may be easily confused with granulations due to toxic states (Plate XVI, F, G). These granules stain a dark lilac color with Wright-Giemsa stains and have been seen in patients with various types of bone and cartilage abnormalities.<sup>167,176,178,182</sup> However, they are most commonly seen in association with Hurler's syndrome, Hunter's syndrome, and Maroteaux-Lamy polydystrophic dwarfism.<sup>171</sup>

Similar inclusions may be seen in blood lymphocytes ("Gasser's cells") and in blood monocytes.<sup>168,178</sup> The lymphocyte inclusions stain dark red or purple with May-Grunwald-Giemsa stain and metachromatically with toluidine blue, while normal azurophilic granules do not stain at all.<sup>178</sup> Such lymphocyte granules are found in all types of mucopolysaccharidoses except Morquio's syndrome, but they are most frequent in the Hurler, Hunter, Sanfilippo, and Maroteaux-Lamy syndromes.<sup>171,178</sup> They tend to occur in clusters rather than diffusely throughout the cytoplasm, are surrounded by vacuoles, and are shaped like a dot or comma.<sup>178</sup> In one series of 19 patients, from 8 to 50% of the lymphocytes contained the inclusions, and their presence was thought to be of diagnostic significance.<sup>178</sup>

These inclusions are seen inconstantly in the blood, but are more common in the bone marrow. For example, of a series of 18 pa-

tients with Hurler's form of mucopolysaccharidosis, Alder-Reilly bodies were present in the blood of less than 10%. However, careful examination of the bone marrow revealed mucopolysaccharide granules in large mononuclear cells ("Bukot's cells") in 17 of the 18 patients.<sup>170,181</sup>

The type of inclusion seen is not diagnostic of a particular type of mucopolysaccharidosis; neither is the frequency of the inclusions correlated with clinical severity.<sup>174</sup> It is now clear that the basic defect in this group of diseases lies in the incomplete degradation of the protein-carbohydrate complexes known as mucopolysaccharides, and in the different forms of mucopolysaccharidosis there appear to be different enzymatic deficiencies.<sup>171</sup> The accumulation of partially degraded mucopolysaccharide within lysosomes has been demonstrated by electron microscopy<sup>171</sup>; the degradation of the protein core of the mucopolysaccharide appears to proceed normally, but catabolism of the carbohydrate (glycan) branches is impaired.

### May-Hegglin Anomaly

The May-Hegglin anomaly is a rare, dominantly inherited disorder characterized by large (2 to 5  $\mu$ m), well-defined, basophilic and pyroninophilic inclusions in granulocytes (neutrophils, eosinophils, basophils, monocytes) and accompanied by variable thrombocytopenia and giant platelets containing few granules.<sup>190</sup> For the most part, affected family members have not been ill, but occasionally abnormal bleeding has occurred.<sup>194,199,200</sup> Clot retraction time is prolonged and the reaction to the tourniquet test may be positive. Platelet survival was short (1½ three days as compared with the normal,  $6.9 \pm 1.5$  (1 SD) days).<sup>193</sup> Platelet aggregation and retraction were found to be normal, but spreading and serotonin uptake were increased.<sup>197</sup> Enzyme and substrate content per platelet was increased, but was decreased as related to platelet volume.<sup>197</sup> The granulocyte inclusions (Fig. 42-3) are similar to Dohle bodies (page 1279) in appearance, but often are larger, more round and discrete, and may

formed in most granule-containing cells throughout the body.<sup>213</sup> The resulting abnormalities can be found in the hematopoietic tissues, hair, ocular pigment, skin, adrenal glands, pituitary gland, gastrointestinal organs, peripheral nerves, and elsewhere.<sup>213</sup>

In *neutrophils* the anomalously large, peroxidase-positive granules seen by light microscopy<sup>209,219</sup> have been shown by electron microscopy to be abnormal primary (azurophilic) granules, the contents of which remain pleomorphic, the normal granule crystalloid structure not being formed.<sup>213,217</sup> The specific granules are normal.<sup>213</sup> There appears to be an increased tendency to autophagic vacuole formation in Chediak-Higashi neutrophils, perhaps due to increased permeability and leakage of injurious materials from the massive granules.<sup>235</sup> There is only one type of granule in normal eosinophils and in Chediak-Higashi individuals these are abnormal also.<sup>213</sup> Chediak-Higashi granules also have been demonstrated in mononuclear cells, but their mode of formation is not well understood. In lymphocytes and plasma cells they may be primary granules, but in mononuclear phagocytes and lymphocytes they may be phagolysosomes.<sup>235</sup> Abnormal granules have been observed less frequently in erythroid cells, while in megakaryocytes and platelets the granules appear to be normal.<sup>213</sup>

Similar large granules containing a glycolipid have been observed in the Schwann cells of peripheral nerves, in neurons in the central nervous system,<sup>233,237</sup> in renal tubular cells,<sup>237</sup> and in the vascular endothelium and fibroblasts.<sup>205</sup> In addition, giant pigment granules have been demonstrated in melanosomes<sup>237</sup> and in hair strands.<sup>205,237</sup> In the several different tissues affected, the consistent feature has been that the histochemical reactions of the large abnormal granules are those usually seen in normal granules of that cell line.<sup>237</sup> Since there appears to be no alteration in granule enzyme content, the defect may be in the structure of the lysosome wall. In any case, the effects of the abnormality in different tissues depend on granule function in that tissue. Thus, the large but fewer melanin granules pro-

duce "pigment dilution" and this explains the peculiar hair color, partial albinism, photophobia, and nystagmus.<sup>237</sup> On the other hand, the abnormal, large granules in neutrophils (Plate XVI, H) lead to increased susceptibility to infection. Infection occurs in spite of an above-normal rate of phagocytosis and a normal postphagocytic metabolic burst ( $H_2O_2$  production, etc.).<sup>229</sup> Apparently the intracellular destruction of some bacteria by Chediak-Higashi leukocytes is delayed because the postphagocytic delivery of lysosomal enzymes into phagosomes is inefficient and incomplete.<sup>233</sup> In addition, a defect in cellular response to chemotactic stimuli both *in vitro* and *in vivo* in skin windows has been demonstrated in man and in the mink.<sup>210,211</sup> Finally, in the late stages of the disease, leukopenia and inadequate granulocyte reserves may decrease resistance to infection.<sup>206</sup> The mechanism for this may relate to a postulated destruction of granulocytes within the marrow<sup>206</sup> or to the effects of the large spleen, or because of marrow infiltration by mononuclear cells during the accelerated phase.

**INHERITANCE.** Fifty-six affected children have been reported in families with a total of 127 children.<sup>205</sup> Judging by this and on the basis of animal studies,<sup>228</sup> this disorder is almost certainly inherited as an autosomal recessive trait. Males and females have been affected in a ratio of 0.87:1. A high proportion of marriages producing affected children have been consanguineous. Some heterozygotes may be identifiable by the presence of granulation in some of their lymphocytes.<sup>215,226</sup>

**CLINICAL FEATURES AND COURSE.** As already mentioned, the partial albinism (more properly, pigment dilutional defect<sup>237</sup>), "silvery" hair (Plate XVI, L), and photophobia are usually noted early in infancy. The poor resistance to respiratory and cutaneous infection, especially by staphylococci and other gram-positive organisms, soon becomes evident. In four patients studied for more than one year there were 29 episodes of fever and pyogenic infection.<sup>240</sup> Many of the afflicted children die of infection during infancy or

early childhood. In others the disease remains quiescent or changes to an "accelerated" phase characterized by lymphadenopathy, hepatosplenomegaly, neuropathy, anemia and neutropenia (90%), and less often thrombocytopenia (67%). During this phase there is widespread infiltration of the tissues by mononuclear cells; this has been termed "lymphoma" by some, but it is more likely a reactive lymphohistiocytic response.<sup>205,222</sup> During the accelerated phase, neurologic manifestations (peripheral neuropathy) may become prominent and hemorrhage may occur.

**LABORATORY FINDINGS.** The characteristic microscopic findings are the large, often multiple, peroxidase-positive lysosomal granules in the granulocytes of the blood and bone marrow, and the large melanosomes in the hair. Less frequent are granules in the lymphocytes. During the early phases of the disease, blood counts give normal values, but as the disease progresses anemia, neutropenia, and thrombocytopenia frequently develop. Immunoglobulin and complement levels are normal as are cellular immune reactions. Later, in the accelerated phase, erythrocyte and granulocyte survival may be shortened.<sup>205</sup>

**MANAGEMENT.** The infections, when they occur, are managed according to generally accepted medical principles. The prophylactic administration of antibiotics has not proved to be beneficial.<sup>240</sup> In the accelerated phase, splenectomy has been only temporarily helpful<sup>205</sup>; best results have been obtained with a combination of vincristine and prednisone therapy, but only a few patients have been so treated.

#### Abnormal Specific (Secondary) Granule Formation

A syndrome of lifelong recurrent staphylococcal skin and sinus infections associated with abnormal chemotaxis, impaired staphylococcal killing, and morphologic abnormalities in the neutrophils was described in a 14 year old boy.<sup>250</sup> No other family members

were affected. The patient's polymorphonuclear neutrophils exhibited bilobed nuclei with unevenly distributed chromatin, drumstick-like nuclear projections, and nearly absent cytoplasmic granules that stained with peroxidase but not with alkaline phosphatase. On electron microscopy, primary granules were present, but specific granules were small and reduced in number. These neutrophils were capable of phagocytosis, generated  $H_2O_2$ , reduced NBT dye, and killed *Candida*, but staphylococcal killing was impaired.

#### Familial Vacuolization of Leukocytes (Jordan's Anomaly)

This disorder is characterized by the presence of vacuoles in the cytoplasm of granulocytes, monocytes, and occasionally in lymphocytes and plasma cells. In members of one family, all of the blood neutrophils and more than 70% of the monocytes contained 3 to 10 vacuoles ranging in size from 2 to 5  $\mu m$ , while fewer and smaller vacuoles were seen in eosinophils, basophils, and lymphocytes.<sup>246</sup> By histochemistry and fluorescence microscopy the vacuoles were shown to contain lipids. These were seen in promyelocytes, myelocytes, metamyelocytes, and occasionally in plasma cells in the bone marrow; they were not present in myeloblasts, erythroblasts, or megakaryocytes.<sup>246</sup> The disorder appears to be familial. Two members were affected in each of two unrelated families.<sup>245,246</sup> There was no acute disease in any of the four patients, but, in members of one of the families, progressive muscular dystrophy was present,<sup>246</sup> while, in members of the other, ichthyosis was associated.<sup>245</sup> This type of vacuolization must be distinguished from that characterized by fat-staining vacuoles occurring in persons with serious infections, toxic hepatitis, or diabetic ketoacidosis<sup>245</sup> (also see Chapter 41, page 1278).

#### Other Inclusions in Leukocytes

In an infant with congenital bile duct atresia, amorphous, round to oval bodies that stained green or gray-green with Romanow-

sky stains were seen in 3 to 13% of the blood neutrophils and in 1 to 5% of the monocytes.<sup>218</sup> Similar inclusions were present in all stages of myeloid cells in the bone marrow but not in lymphocytes or plasma cells. Electron microscopy showed that the inclusions were not enclosed in a phagocytic vesicle.

In the blood monocytes of patients with the Hermansky-Pudlak syndrome,<sup>251</sup> a rare familial disorder characterized by albinism, mild bleeding due to platelet dysfunction, and accumulation of ceroid-like pigment in marrow macrophages, lipopigment bodies as well as another type of inclusion were demonstrated.

### Hereditary Giant Neutrophilia

Neutrophils with a diameter of about 17  $\mu\text{m}$  (as compared to a normal diameter of about 13  $\mu\text{m}$ ) are rare in blood smears from normal people (one in 20,000 neutrophils or less). They may be seen with greater frequency in patients who are ill, but even then the number rarely exceeds 0.2% unless a disease involving leukocyte production is present or a reaction to a cytotoxic drug occurs.<sup>216</sup> A family with giant neutrophils in healthy members of three generations has been reported.<sup>255</sup> Over several years the propositus had an average of 1.6% giant neutrophils in his blood. The large neutrophils appeared to be nearly double the normal cell volume and contained from 6 to 10 nuclear lobes. Because of this it was suggested that the cells may have been tetraploid. This anomaly appeared to be transmitted as an autosomal dominant trait.

### Hereditary Hypersegmentation of Neutrophil Nuclei

Several families whose members had a hereditary (autosomal dominant) increase in the number of neutrophil nuclear segments have been described.<sup>262</sup> The proportion of neutrophils containing five lobes or more exceeded 10% in most heterozygotes and was greater than 14% in several suspected homozygotes, as compared to no more than 10% in normal controls.<sup>262</sup> The bone marrow

findings suggested a tendency to nuclear indentation in early myeloid forms (eosinophils and basophils as well as neutrophils).<sup>262</sup> The normal size of these neutrophils was thought to provide evidence against tetraploidy, but in one study of five female family members the mean number of nuclear drumsticks appeared to be increased above normal.<sup>260</sup> The chief significance of this anomaly is in its differentiation from other causes of hypersegmentation such as folate or vitamin B<sub>12</sub> deficiency (page 568).

### Hypersegmentation of Eosinophils and Negative Staining for Peroxidase and Phospholipids<sup>272</sup>

This disorder is inherited as an autosomal recessive trait and is characterized by a lack of sudanophilia and peroxidase activity in all of the eosinophils, whereas these histochemical reactions remain positive in the neutrophils and monocytes.<sup>270</sup> In addition, the number of eosinophilic granules per cell appears to be reduced and there may be some hypersegmentation of the eosinophil nucleus. No disease accompanies the disorder and to date it has been reported only in people of Jewish (predominantly Yemenite) extraction. However, members of other races have not been studied adequately.

## Functional Disorders of Leukocytes Not Characterized by Morphologic Changes

### Chronic Granulomatous Disease (CGD) of Childhood<sup>281,297,303</sup>

This disorder represents a lethal, inherited defect of leukocyte function which is associated with no evident morphologic abnormalities. Its exact nature is not yet understood and, indeed, it is likely that several different enzymatic defects result in a similar clinical and pathologic picture (see Variants, page 1328). In affected males there is a history, beginning in early childhood, of recurrent suppurative infections caused by organisms

of low-grade pathogenicity, such as *Serratia marcescens*, enterobacteria (*Klebsiella*, *Aerobacter*, or *Salmonella*), or by staphylococci. The eczematoid, granulomatous and sometimes purulent skin infections recur over and over again and clear slowly. Associated adenopathy develops and may persist, giving a picture of *scrofula*. Pulmonary and other infections (eg, osteomyelitis) also are common and progressive granulomatous disease of the lungs, liver, and other sites develops. Hepatosplenomegaly is common and biopsy reveals necrotizing granulomas, often with associated purulent inflammation. The disorder usually progresses to death in early childhood,<sup>283</sup> but occasional patients have survived into the late teens.<sup>284,312</sup> Although rare, this disorder has assumed great importance as a prototype of defects in leukocyte bactericidal capacity.

**HISTORY AND MODE OF INHERITANCE.** The syndrome was first described in 1957<sup>283</sup> as affecting only males. More than 90 cases have now been reported.<sup>303,312</sup> X-linked inheritance has been established. Female heterozygotes are identifiable by the presence of defective leukocyte bactericidal capacity intermediate in degree between that of affected patients and that of normal individuals.<sup>323</sup> Measurements of postphagocytic release of <sup>14</sup>CO<sub>2</sub> from glucose-1-<sup>14</sup>C or reduction of nitroblue tetrazolium (NBT) dye can also be used to detect the defect. By means of the NBT dye test it was found that in carrier females there is a mixed population of neutrophils, about half being NBT negative and half positive (Table 42-2). The defect appears to be transmitted on an X chromosome and the degree of deficit in females varies according to random X chromosome inactivation. Consequently, one may expect to find an occasional carrier female with clinical disease as severe as that in the males.<sup>294,323</sup>

**ETIOLOGY AND PATHOGENESIS.** Because of the clinical and pathologic picture of chronic recurrent infection caused by low-grade pathogens and the resultant granuloma formation, it was suggested that a defect in the inflammatory response results in lesions

**Table 42-2. Proportion of Postphagocytic Neutrophils That Are NBT Positive in Family Members and Patients with Chronic Granulomatous Disease as Compared to Normals<sup>323</sup>**

	Number	% NBT Positive Cells*
Patients (hemizygotes)	7	9.9 ± 4.2
Mothers & grandmothers (heterozygotes)	9	49.8 ± 5.4
Carrier sisters	7	51.3 ± 6.6
Fathers, brothers, and normal sisters	18	74.4 ± 5.4
Normals	12	89.5 ± 5.4

\*Mean ± 2 SD

comparable to those that normal persons develop following infection with tubercle bacilli or brucella.<sup>297</sup> No abnormality in antibody response to diphtheria, tetanus, or polio virus was demonstrated in these patients, and their delayed hypersensitivity response also was normal.<sup>297</sup> In addition, leukocyte migration and surface phagocytosis were normal.<sup>297</sup> Nevertheless, when leukocytes of CGD patients were incubated with bacteria, such as staphylococci, *Serratia*, or other organisms causing infection in these patients, decreased bacterial killing and prolonged bacterial survival in the phagocytic vacuoles were noted.<sup>307,317</sup> Decreased killing of fungi and incomplete inactivation of vaccinia and herpes virus have also been reported,<sup>297,311</sup> but streptococci are killed normally by CGD leukocytes.<sup>305,317</sup>

Although the mechanisms of bacterial killing by normal leukocytes are incompletely understood, it is clear that phagocytosis is followed by fusion of lysosomes with the phagocytic vacuole, discharge of lysosomal enzymes into the phagosome, and a burst of postphagocytic metabolic activity. These events are usually accompanied by bacterial death and digestion (see page 259, Chapter 6). Initial studies of CGD leukocytes suggested that the defect in bacterial killing might result from decreased degranulation and delivery of lysosomal enzymes into phagocytic vacuoles.<sup>297,317</sup> However, other

studies demonstrated normal lysosomal degranulation.<sup>277,307</sup> In still other experiments, smaller than normal phagosomes without normal enlargement<sup>314</sup> were described. Attempts to demonstrate a deficiency of lysosomal enzymes have been unsuccessful, normal activities of acid phosphatase, beta glucuronidase, peroxidase, lysozyme, and phagocytin having been found.<sup>297,317</sup> A deficiency of cytoplasmic NADH oxidase activity was reported in five patients with CGD and it was suggested<sup>275</sup> that this deficiency might explain the observed defects in post-phagocytic oxygen consumption, oxidation of glucose via the hexose monophosphate shunt (release of  $\text{CO}_2$  from the 1-carbon of glucose), formate oxidation, NBT dye reduction, and bacterial killing.<sup>298-314</sup> On the other hand, others have not found a deficiency of NADH oxidase activity,<sup>299</sup> and it has been reported that a deficiency of NADPH oxidase or an abnormality in its activation is the underlying cause of this syndrome.<sup>297a</sup> In either case, the finding that iodination of bacteria in the phagosome appears to be one mode of bacterial killing, and that this is defective in CGD leukocytes and can be partially repaired by the insertion of an oxidase into the phagosome, either carried in on oxidase-coated polystyrene particles<sup>278,302</sup> or as part of the ingested bacteria,<sup>309</sup> provides strong evidence incriminating defective generation of  $\text{H}_2\text{O}_2$ , superoxide,<sup>247</sup> or related ions<sup>290a</sup> as the pathogenic defect in this disorder.<sup>275,278</sup> Although most studies have involved the neutrophils, it was recognized in the earliest reports that lipid-laden macrophages were present in the granulomatous lesions<sup>310</sup> and a defect in the mononuclear phagocytes<sup>290</sup> and in eosinophils<sup>314</sup> has since been demonstrated. The platelets apparently are normal.<sup>292</sup>

Since the generation of peroxide and bacterial killing may involve several enzymes (myeloperoxidase, NADH or NADPH oxidase, glutathione peroxidase, glutathione reductase, and the enzymes of the hexose monophosphate shunt), one might expect that defects other than NADH or NADPH deficiency would result in a disorder pheno-

typically like that of CGD. Several have already been described (see Variants, below).

**CLINICAL AND LABORATORY FEATURES.** The clinical picture of chronic granulomatous disease, as mentioned earlier, includes the development of recurrent infections, especially of the skin and lungs, with septic lymphadenitis, development of hepatosplenomegaly and granulomas, and ultimately death from infection.<sup>283,284,297</sup>

The blood neutrophil count is not reduced and rises appropriately with infection or after endotoxin injection; monocytosis is sometimes observed.<sup>297</sup> Since chronic infection is common, the immunoglobulin levels often are elevated, and plasma cells may be present in increased numbers in the bone marrow. Immunoglobulin deficiencies have not been encountered and antibody titers (both IgM and IgG) increase normally after antigenic stimulation. Reticuloendothelial clearance of colloidal gold also is normal. Peroxidase staining of blood cells demonstrates more intense dye uptake in CGD neutrophils than in normal cells.<sup>311</sup> The simplest method for detecting the defect is the postphagocytic, intraphagosomal reduction of almost colorless NBT dye to blue-black formazan (Fig. 42-4).<sup>276,314</sup> When properly standardized in regard to time of incubation of leukocytes with the dye-tagged zymosan particles, affected patients and most carriers are readily recognized (Table 42-2). When the reaction to this test is negative in suspected carriers the reaction to the quantitative dye reduction test will usually be positive.<sup>311</sup>

**COURSE AND PROGNOSIS.** This disease runs a progressive downhill course due to repeated infections and granuloma formation. The average life expectancy is five to seven years.<sup>297</sup>

**VARIANTS.** Since the clinical picture of chronic granulomatous disease results from delayed killing of catalase-positive bacteria, enzymatic defects in the bactericidal system other than decreased oxidase (NADH or NADPH) activity (Chapter 6, page 259) may produce an almost identical picture.

Fig. 42-4 Phase (A and C) and bright field (B and D) photomicrographs of normal neutrophil (A and B) and a neutrophil from a patient with chronic granulomatous disease (C and D). In A and B, note NBT reduction (black area) that has occurred in the normal neutrophil 20 minutes after ingestion of zymosan granules and NBT dye. In C and D zymosan ingestion is normal but there is no dye reduction (From Nathan, Baehner, and Weaver,<sup>314</sup> courtesy of the authors and the Journal of Clinical Investigation)

*Glutathione peroxidase deficiency* was found in two unrelated females, 9 and 13 years old, presenting a clinical and metabolic picture similar to that of chronic granulomatous disease and with decreased bactericidal capacity.<sup>299</sup> The findings in these girls differed from those in males with CGD only in that no heterozygotes were detected in their families and their clinical course was somewhat milder.

*Lipochrome histiocytosis* was described in three sisters with rheumatoid arthritis, hyperglobulinemia, splenomegaly, pulmonary infiltrates, and increased susceptibility to infection.<sup>296</sup> No granulomas were found in tissue biopsies, but lipochrome pigmentation in large macrophages was present throughout the tissues. Studies of blood leukocyte func-

tion in two of the sisters revealed impaired postphagocytic respiration, NBT reduction, and hexose monophosphate shunt activity identical to that seen in chronic granulomatous disease.<sup>318</sup>

A bactericidal defect has also been described in a patient with a complete deficiency of *glucose-6-phosphate dehydrogenase* (G-6-PD)<sup>286</sup> (Chapter 23). Apparently almost complete absence of G-6-PD activity is necessary to interfere with bacterial killing since no difference from normal could be detected in cells with 25% activity or greater.<sup>319</sup>

"*Job's syndrome*" was reported as occurring in two unrelated girls with red hair and fair skin who suffered from repeated staphylococcal cold abscesses, sinusitis, eczema, and pulmonary disease, a syndrome not unlike the

affliction of Job.<sup>288</sup> The leukocytes of these patients were capable of normal phagocytosis, bacterial killing, NBT reduction, and iodine fixation,<sup>289,321</sup> unlike those of patients with CGD. An additional case of Job's syndrome was reported in 1971.<sup>315</sup> Two sisters, the children of parents who are second cousins; also have been reported as having this disease,<sup>281</sup> but they probably did not have it since their leukocytes did not reduce NBT or kill bacteria normally.

Hydrocortisone produces a defect in bacterial killing by neutrophils that is similar to that seen in chronic granulomatous disease.<sup>313</sup>

### Myeloperoxidase Deficiency

An inherited (probably autosomal recessive) deficiency of myeloperoxidase (MPO) in the neutrophils and monocytes, but not the eosinophils, has been described.<sup>331</sup> The 49 year old male propositus, one of his two sisters, and all four sons exhibited decreased MPO activity, but no increased frequency of infections accompanied this defect. Also in two other families apparently similarly affected, infection was not a problem.<sup>334</sup> These findings indicate that mechanisms other than MPO-catalyzed bacterial killing are functionally important in human neutrophils.<sup>331</sup>

A similar but acquired defect in MPO activity was reported in a patient with myelomonocytic leukemia<sup>330</sup> and in another with a refractory anemia.<sup>335</sup>

### Other Enzymatic Defects

Two siblings with negative peroxidase, oxidase, and lipid reactions in the neutrophils and monocytes also have been reported.<sup>332</sup>

## Disorders Involving the Monocyte-Macrophage System

The abnormalities to be discussed here include the familial sphingolipidoses and those conditions, sometimes acquired, that may simulate them in that "storage" cells

may be found in the bone marrow, blood, or other tissues. Most of these disorders are the result of inherited enzymatic defects. Thus they are not, strictly speaking, diseases of the monocyte-macrophage system. However, their major manifestations often result from accumulation of incompletely catabolized tissue products in the cells of this system and therefore it seems appropriate to include them here. They are of interest to the hematologist since, in some of them (eg, Gaucher's disease, Niemann-Pick disease), anemia, leukopenia, thrombocytopenia, or hepatosplenomegaly may be the mode of presentation. In others (sea-blue histiocyte syndrome, lipochrome histiocytosis) the presence of pigment-containing cells in the bone marrow, lungs, or other sites, or skin lesions simulating petechiae (Fabry's disease, Fig. 42-10A, page 1341) may bring them to his attention.

Still other disorders such as Tay-Sachs disease, although closely related biochemically (Fig. 42-6B), primarily involve the nervous system and the hematologist is seldom consulted.

**PATHOGENESIS.** The fundamental defect in all of these lipidoses is the accumulation of ceramide compounds in various cells and tissues. Ceramide is an acylated sphingosine (Fig. 42-5A and B) and is the backbone of a variety of compounds, called sphingolipids, that have major structural functions in many cells. The fatty acid portion of sphingolipid differs in various tissues, being mainly stearic acid ( $C_{18}$ ) in the brain and somewhat longer fatty acids ( $C_{20}$  to  $C_{24}$ ) in non-neural tissue. The distinguishing feature and function of each sphingolipid are determined by the compound(s) esterified to the number one-carbon of ceramide (Figs. 42-5A and 42-6). For example, the addition of hexoses and *n*-acetylneuraminic acid to ceramide forms the group of compounds known as gangliosides that are found chiefly in the brain (Fig. 42-6B). Other ceramide compounds, the globosides (Fig. 42-6A), are found in cell membranes, including those of erythrocytes, leukocytes, and platelets, where they function as haptens and may be important in defining the immunochemical specificity of the cell surface.<sup>343</sup>

Fig 42-5. Formulae of some of the sphingolipids

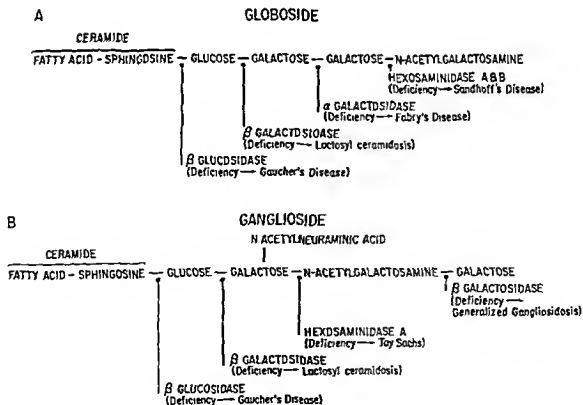

Fig. 42-6 Schematic structure of globoside and ganglioside to show site of action of the several catabolic enzymes, which, when defective, result in one of the storage diseases

Blood group antigens also are ceramide compounds; thus, H-isoantigen is:

Theoretically these lipids may accumulate as a result of: (1) increased synthesis within cells, (2) increased uptake from outside sources; (3) a chemical defect in the lipid that interferes with catabolism, (4) a defect in lipid catabolic enzymes; or (5) combinations of these mechanisms. In the hereditary lipidoses, studies have revealed no evidence for overproduction of lipid,<sup>421</sup> but clear-cut deficiencies in specific catabolic enzymes have been well documented.<sup>310,311</sup> On the other hand, in some of the acquired disorders no enzymatic defects have been demonstrated and an overloading of normal lipid catabolic mechanisms seems likely (see page 1336). Regardless of the basic mechanism, one would expect that the tissues most seriously affected would be those in which lipid turnover is high, either because of normal metabolic requirements, as in the developing nervous system, or where lipid catabolism is a major cell function as a result of phagocytosis and scavenging activity, as in the monocyte-macrophage system. Thus, indeed, appears to be the case.

### Gaucher's Disease

**DEFINITION AND HISTORY.** Gaucher's disease is a rare, chronic, familial disorder characterized clinically by hepatosplenomegaly,

skin pigmentation, pingueculae of the sclerae (Fig. 42-7), bone lesions, and, in its later stages, anemia, leukopenia, or thrombocytopenia. Histologically, large cerebroside-containing cells (Fig. 42-8 and Plate II, G, p. 72) are found, particularly in the spleen but also in the bone marrow, liver, and elsewhere.<sup>371</sup> The condition was described by Gaucher in 1882<sup>383</sup> and the presence of glucocerebroside in the cells, first recognized by Epstein<sup>381</sup> and by Lieb<sup>403</sup> in 1924, has since been amply confirmed.<sup>415</sup> That the metabolic defect in Gaucher's disease is deficient activity of a catabolic enzyme,  $\beta$ -glucocerebrosidase, was established by Brady and associates (Fig. 42-6).<sup>369</sup>

**ETIOLOGY AND PATHOGENESIS.** Gaucher's disease is most often discovered during childhood. A considerable proportion of the patients have been Jews, especially those from the Baltic Sea area, but the condition has been found in non-Jewish Caucasians and in natives of Greece,<sup>375</sup> India, China, and Japan; it has also been reported in Negroes.<sup>371,390,393</sup> Commonly, several cases are found in a family,<sup>374</sup> but it is unusual for more than one generation to be affected. There is no preference for either sex. From the more than 1000 cases of Gaucher's disease reported, it has been inferred that the mode of inheritance is autosomal recessive.<sup>345</sup> This was substantiated by cell culture techniques whereby tissues from patients with Gaucher's disease were shown to have markedly decreased  $\beta$ -glucosidase activity.<sup>347,364</sup>

Fig 42-7. Pingueculae in a patient with Gaucher's disease

Fig 42-8. Typical Gaucher cell together with a lymphocyte and a juvenile neutrophil from the sternal bone marrow in a patient with Gaucher's disease

The enzyme activity in carriers was intermediate between the normal level and that found in affected patients.<sup>347,394,395</sup> Some family studies, however, have suggested occasional dominant transmission.<sup>390,398</sup> It has been proposed that this may have resulted from marriage between an affected person and a heterozygote.<sup>345,399</sup> The assay of  $\beta$ -glucosidase activity in such kindreds should reveal whether adult Gaucher's disease is ever transmitted as an autosomal dominant trait.

Two different  $\beta$ -glucosidase activities, possibly representing different isozymes, with different pH optima (4.0 and 5.3) have been found in leukocytes from adults with Gaucher's disease.<sup>364,395</sup> However, in skin fibroblast cultures from these patients only one enzymatic activity was detected.<sup>364</sup>

As a result of deficiency in  $\beta$ -glucocerebrosidase activity,<sup>369</sup> cleavage of glucose from ceramide is impaired (Fig. 42-6) and glucose-ceramide accumulates within cells where it is apparently is largely confined within lysosomal membranes.<sup>350</sup>

In the adult form of Gaucher's disease the major source of the accumulated glucocerebroside in the tissues appears to be senescent leukocytes.<sup>340,400</sup> Compared with erythrocytes, neutrophils contain about 400 times as much glycolipid per cell, chiefly as ceramide dihexoside.<sup>343</sup> From daily cell turnover rates it has been calculated that granulocyte turnover requires the synthesis and catabolism of nearly 400 mg ceramide lactoside per day, 20 to 40 times as much as is involved in erythrocyte turnover per day.<sup>340</sup>

In patients with the infantile form, glucocerebrosidase activity in the tissues is very low (0 to 9% of normal) in contrast to the adult form in which activity is 12 to 44%.<sup>341</sup> In the infantile form, the central nervous system is the major site of involvement. It is not yet clear whether or not the accumulation of lipid in neurons is followed by cell degeneration, phagocytosis, and transport of these lipids to the spleen, liver, and elsewhere by macrophages, but such a process may at least add to the other sources of glycolipid in the reticuloendothelial system.

**SYMPTOMATOLOGY.** In general, the onset of Gaucher's disease is earliest and progression is most rapid in patients with the least glucocerebrosidase activity. The enzyme level and clinical picture have been found to be relatively constant in a given family, thus suggesting that the disorder is genetically heterogeneous; perhaps several different mutations affect the same or similar loci and alter the composition of the enzyme.<sup>364</sup>

Gaucher's disease has been divided into three forms—infantile, juvenile, and adult—based on the time of appearance of clinical symptoms,<sup>367,409</sup> but some do not differentiate the juvenile and adult forms since they appear to differ mainly in their rate of progression.<sup>341</sup>

The adult type is by far the most common, more than 900 cases having been reported.<sup>345</sup> The term "adult" is somewhat of a misnomer because symptoms usually begin in childhood or early adulthood. Physical development often is normal. Splenomegaly usually is the outstanding sign.<sup>406</sup> It may be discovered

accidentally or because of abdominal fullness; more rarely the weight of the large spleen produces a dragging sensation, or infarction with sharp pain may develop. The liver usually is also enlarged, but there is little enlargement of the superficial lymph nodes. Infrequently, splenomegaly is inconspicuous or absent, and anemia, thrombocytopenia, bone lesions, or other findings lead to the diagnosis.<sup>365,406 409 414</sup> Ascites is rare.<sup>399</sup> Hemorrhage, especially from the nose and gums, is relatively common and occasionally petechiae or purpuric spots are noted.

Skin pigmentation, ochre to brown in color with a yellow or leaden hue, was found in 45 to 75% of patients in some series.<sup>367</sup> The head, neck, and hands were affected and symmetrical pigmentation of the legs from just below the knees to the instep was described.<sup>367</sup> In other reports, however, skin pigmentation and brown pingueculae (Fig. 42-7) were described only in a minority of patients and were said to appear when the disease was at an advanced stage.<sup>406</sup> The pingueculae contain the typical Gaucher cells.<sup>380</sup>

The accumulation of Gaucher cells in the bones may be associated with macroscopic areas of destruction. The cells may be found in the femur, hip bones, vertebrae, humerus, or tibia<sup>381 416</sup> and are seen roentgenographically in about 75% of the patients. The femur is most commonly involved, especially its head and neck; the swelling in its lower end often resembles an Erlenmeyer flask in shape.<sup>419</sup> The bone may be increased in diameter and the cortical layer thinned<sup>367</sup> or there may be areas of rarefaction and condensation. Although only 50% of patients with bone lesions have symptoms referable to the bones,<sup>419</sup> severe pain in the limbs,<sup>408,409</sup> crippling,<sup>406</sup> and collapse of vertebral bodies with gibbus or pathologic fractures may occur.<sup>408,414</sup>

A much less common form of Gaucher's disease is that seen in *infants*. This is characterized by retarded development, early onset of neurologic signs (convergent strabismus, dysphagia, opisthotonos, and multiple signs of brain stem involvement), hepatosplenomegaly,<sup>341,345,347</sup> cachexia, and death—

usually before the age of 2 years. Bone involvement is rarely, if ever, present in these patients.<sup>388</sup> This form also is transmitted as an autosomal recessive trait and often is found in several members of a family. Consanguinity is not uncommon. The infantile type of the disease rarely occurs in Jews.<sup>369,406</sup>

The third, somewhat heterogeneous type (*juvenile Gaucher's disease*) was reported in several interrelated families in Sweden.<sup>394</sup> The onset took place when the patient was six months to a year of age, but cerebral signs appeared later than in the infantile type and 6 of the 12 patients survived into late childhood or the teens.

**THE BLOOD.** The *anemia* is usually moderate in degree and normocytic in type. There is little or no evidence of active blood regeneration such as polychromatophilia or nucleated red cells. In one patient with massive splenomegaly, the red cell mass was normal but the plasma volume was increased, thus it was inferred that the anemia was due to hemodilution.<sup>368</sup> In four other patients a mild decrease in red cell survival was accompanied by decreased incorporation of iron into red cells, and it was concluded that the anemia resulted from a moderate degree of ineffective erythropoiesis.<sup>402</sup> In addition, there undoubtedly is considerable red cell sequestration in the large spleen. *Leukopenia* is common but is of little clinical importance since resistance to infection does not seem to be impaired.<sup>406</sup> *Thrombocytopenia* is present in the majority of patients and can be the most troublesome hematologic manifestation.<sup>406</sup> It is usually mild with platelet counts above  $70.0 \times 10^9/l$ , but sometimes severe thrombocytopenia with bleeding may develop.<sup>376,389</sup> In one such patient the platelet half-disappearance time was reduced to 0.8 days and there was marked sequestration of labeled platelets in the spleen. After splenectomy the  $t_{1/2}$  increased to five days and the platelet count rose to normal levels.<sup>386</sup> Gaucher's cells have been demonstrated in the blood, but this usually requires careful examination of buffy coat preparations.<sup>366,385</sup>

The *serum acid phosphatase* activity, when

measured with phenyl phosphate as substrate, usually is increased.<sup>406,421,425</sup> Several isozymes have been detected; some apparently are the same as those found in normal spleen and platelet lysosomes.<sup>421</sup> In contrast to the prostatic enzyme, the acid phosphatase in the serum of patients with Gaucher's disease is less inhibited by 1-tartrate.<sup>406,421</sup> The cytoplasm of Gaucher's cells shows strong acid phosphatase activity.<sup>373,417</sup>

Monoclonal immunoglobulin peaks have been described in a number of patients with adult Gaucher's disease, but their significance remains obscure.<sup>413</sup>

**DIAGNOSIS—THE GAUCHER CELL.** Massive splenomegaly associated with no evidence of cachexia, particularly if accompanied by skin pigmentation, brown pingueculae, bone pain, a tendency to easy bruising, and moderate thrombocytopenia suggests Gaucher's disease. The diagnosis depends on finding the typical Gaucher's cells (Fig. 42-8 and Plate II, G) in biopsied tissue. The cells are present in the bone marrow, but splenic or liver aspirates, lymph nodes, and the kidneys also contain these cells.<sup>371</sup>

In marrow aspirates the cells are most easily detected in the thicker portions of the smear by scanning with a low-power objective. The large diameter (20 to 80  $\mu$ m), pale blue, engorged histiocytes are usually easily found and can then be more carefully examined under higher-power magnification (Plate II, G). They are usually round or oval and may possess one or several eccentrically placed nuclei. The cytoplasm appears faintly blue in Wright's-stained smears or in smears stained with Mallory's aniline blue, and numerous fibrillae can be seen. The cells also stain faintly with eosin and are PAS and Sudan black B positive.<sup>359</sup>

**TREATMENT.** Treatment of patients with the adult form of Gaucher's disease is purely symptomatic. Splenectomy may be considered if the weight of the spleen or splenic infarcts become a problem, but the major indication for splenectomy in these patients is severe thrombocytopenia with bleeding.<sup>386,404</sup> The appearance of Gaucher's cells in extrasplenic organs such as the bones and

liver may be accelerated following this operation.<sup>406,427</sup>

Patients with manifest Gaucher's disease, with rare exceptions,<sup>398</sup> produce only healthy offspring, half of whom will be carriers. Those who already have produced a child with the disease have a 50% chance of producing additional affected offspring.<sup>390</sup> Culture of amniotic fluid cells and assay for  $\beta$ -glucosidase activity permit detection of affected fetuses in families at risk.<sup>341</sup>

Since human and beef spleen preparations of purified exogenous glucocerebrosidase are now available,<sup>340</sup> their administration to patients with very low enzyme levels offers hope for specific therapy. It is reasonable to believe that administered enzyme will be taken up by the reticuloendothelial cells. That the enzyme will be taken up by the central nervous system seems less likely.

Splenic transplantation has been attempted in end-stage, juvenile Gaucher's disease, but the graft functioned for only about 40 days and the patient died three months post-transplantation.<sup>391</sup>

**PROGNOSIS.** Patients with the adult form of Gaucher's disease may live long and successful lives if disease progression is slow, and some have survived to old age.<sup>390</sup> A number have survived pregnancy without difficulty.<sup>397</sup> Long survivals (15 to 30 years) after splenectomy have been recorded.<sup>401</sup> In patients with the infantile form, however, death usually occurs in early childhood. In those with the juvenile form the rate of progression is more rapid than in adult onset disease and the prognosis is particularly poor if there is neurologic involvement.

**PATHOLOGY.**<sup>350</sup> The pathognomonic feature of Gaucher's disease is the infiltration of tissues by Gaucher cells.<sup>377</sup> Under the electron microscope these cells are seen to be filled with numerous, elongated, rod-shaped bodies that contain smooth-walled tubular elements and react with acid phosphatase.<sup>412</sup> They presumably are secondary phagosomes.

In the chronic form of the disease the splenic pulp is densely infiltrated with Gaucher cells. In the liver the cells are found mainly in the centrilobular areas, the Kupffer cells

usually appear to be normal.<sup>350</sup> In the bone marrow the Gaucher cells are often found in large groups and in the lymph nodes they are associated with the reticulum. The spleen often is increased to ten times normal size; weights in excess of 6000 g have been recorded. The liver may be twice normal size.

In the infantile form the lungs, kidneys, adrenals, ovaries, pituitary gland, thymus gland, and brain also are involved. There is acute neuronal degeneration,<sup>360</sup> but little neuronal storage of lipid is evident.<sup>360</sup> Gaucher bodies are only occasionally seen in neurons.<sup>350 360 410</sup>

**GAUCHER CELLS IN OTHER DISORDERS.** Gaucher cells at first were considered pathognomonic of the inherited disorder described above. More recently they have been detected in marrow specimens of patients with chronic myelocytic leukemia (CML), eg, in 10 out of 64 patients in one series.<sup>362</sup> In a patient with CML with a leukocyte count of  $8000 \times 10^9/l$ , electron microscopy revealed typical Gaucher cells. Typical Gaucher cells also have been found in the spleen and bone marrow of a patient with thalassemia major.<sup>420</sup> Of major importance from the standpoint of pathogenesis was the finding that glucocerebrosidase activity in the white cells and spleen of these patients was normal, thereby eliminating the possibility of associated hereditary Gaucher's disease.<sup>400</sup> Sphingolipid turnover resulting from the daily destruction of erythrocytes and granulocytes in normal man is estimated to be 5 to 10 mg for erythrocytes and 350 to 400 mg for granulocytes.<sup>400</sup> In CML with a granulocyte turnover 5 to 10 times normal, or even greater, the sphingolipid load presented to the monocyte-macrophage system each day must be massive. In some patients this load presumably exceeds the catabolic capacity of the normal reticuloendothelial system, thereby producing Gaucher cells.<sup>379</sup>

### Niemann-Pick Disease

**HISTORY AND PATHOGENESIS.** Niemann-Pick disease, a condition similar to the in-

fantile form of Gaucher's disease, was described in 1914<sup>450</sup> and in 1922.<sup>451</sup> Originally thought to occur only in infants, it has since been found that manifestations of this disease may first appear as late as the second year of life and even later (at six years).<sup>440</sup> A few cases of an adult form also have been described.<sup>418 438</sup> There is a marked predilection for inbred populations; 30% of one series of 18 patients<sup>410</sup> and 50% of another series<sup>461</sup> were of Jewish ancestry. Other patient groups have been identified in non-Jewish families in Canada,<sup>459</sup> Switzerland, and elsewhere.

The excess lipid that accumulates in these patients was shown in 1934 to be sphingomyelin.<sup>417</sup> More recently, Brady and co-workers<sup>437</sup> provided evidence of a deficiency of sphingomyelinase and at least two enzymatically distinct forms of Niemann-Pick disease are recognizable.<sup>437,456</sup> From family studies and tissue enzyme assays these disorders appear to be transmitted as autosomal recessive traits.

**SYMPTOMATOLOGY AND PATHOLOGY.**<sup>350</sup> The clinical picture in Niemann-Pick disease probably includes five different but related conditions.<sup>345</sup> All are characterized by infiltration of the tissues with the characteristic foamy storage cells. These cells are round, oval or polyhedral, and 20 to 90  $\mu m$  in diameter. Their cytoplasm is filled with clusters of small, round droplets (Fig. 42-9 and Plate II, H, p. 72), in contrast to the "wrinkled" cytoplasm of the Gaucher cell. The nucleus of the Niemann-Pick cell is small, eccentrically placed, and there seldom is more than one nucleus in a cell. The vacuoles have a faint bluish hue when treated with Wright's stain; staining with PAS and fat stains gives variable reactions.<sup>452</sup>

Under the electron microscope, small lipid bodies (1 to 2  $\mu m$  in diameter) are seen in histiocytes in the lymph nodes and spleen, and membrane-bound inclusions are seen in hepatocytes, Kupffer cells, and in some cells in the central nervous system. The lamellar structure of the inclusions is less striking than in Gaucher cells.<sup>370</sup>

The involved organs show an increase in

Fig. 42-9 Drawings of representative cells in smears made from (A) peripheral blood and (B) sternal bone marrow in a patient with Niemann Pick disease showing numerous vacuoles in the cytoplasm of monocytes (A, 1) and lymphocytes (A 2) in the blood, and foam cells in the marrow (From Kato<sup>444</sup> courtesy of the author and the American Journal of Diseases of Children)

total lipids, especially sphingomyelin (Fig. 42-5D), but also in other phospholipids and cholesterol.<sup>350,435</sup> The chemical changes in the brain are not uniform or specific.<sup>439</sup>

The classical, infantile or A form of Niemann-Pick disease begins in infancy with signs of mental retardation, hepatosplenomegaly, and sometimes lymphadenopathy; and in about half the patients a cherry-red spot can be seen in the macular region of the fundus oculi.<sup>315,440</sup> Most cases of the disease (perhaps 85%) are of the infantile type.<sup>345,452</sup> About half of those affected are persons of Ashkenazi Jewish origin whose ancestors came from the same Baltic region as did the patients with adult Gaucher's or Tay-Sachs disease. Persistent early jaundice, enlarging abdomen, and poor general nutrition are common initial complaints. Enlargement of the liver and lymph nodes occurs early, in contrast to Gaucher's disease. Difficulty in feeding, bronchitis, and bronchopneumonia mark the course; cachexia develops and death usually occurs by the third year of life.

A characteristic ballooning of neurons in both gray and white matter occurs in the central nervous system.<sup>443</sup> By electron microscopy, these neurons were shown to be filled with numerous membranous cytoplasmic bodies containing large amounts of sphingomyelin. The sphingomyelin content of the spleen and liver also was markedly increased.<sup>445</sup> A severe deficiency of sphingomyelinase has been demonstrated in the liver (0 to 7% of normal), in circulating leukocytes (0%), and in cultured skin fibroblasts,<sup>344</sup> as well as in other tissues.<sup>456</sup>

A more chronic, visceral (B) form is characterized by the onset of hepatosplenomegaly in infancy, but prominent nervous system signs do not develop. Thirteen cases of this type have been described.<sup>345</sup> Sphingomyelin also accumulates in the tissues of these patients and they too are deficient in sphingomyelinase.<sup>345,452</sup>

In a third type, onset is delayed until the subject reaches the age of two to four years, but ultimately visceral and nervous system

changes develop and death occurs during childhood or adolescence.<sup>315,452</sup> Neuronal ballooning is as striking as in group A, but, while sphingomyelin and cholesterol are deposited in the viscera, the concentration of phospholipid in gray matter is normal. Sphingomyelinase activity has not been found to be decreased in these patients.

A fourth type (*the D variant*) was described in patients with a common origin in Nova Scotia.<sup>453</sup> Neurologic signs developed in childhood and progression was slow, with death occurring in adolescence. The enzymatic defect has not been established. Foam cells have been found in heterozygous carriers.

A fifth type, designated E, has occurred in a few adults in whom the disease has a mild chronic course with no neurologic manifestations. In these patients also there is marked accumulation of sphingomyelin and cholesterol. The enzymatic defect is unknown.<sup>345</sup>

As with Gaucher's disease it is possible that defects in different isozymes and differing levels of enzymatic activity explain the varied clinical picture.

**THE BLOOD.** Anemia is not conspicuous and when present is only moderate in degree. Leukopenia may be found, and in some patients leukocytosis was present in the absence of infection.<sup>454</sup> Vacuoles in the cytoplasm of lymphocytes and monocytes may be seen even with the light microscope. They are discrete, round, 0.5 to 1.0  $\mu\text{m}$  in diameter, and often are present in groups of 2 to 15 or even 20 per cell (Fig. 42-9). Rarely, they may distend the cell membrane or displace the nucleus. By electron microscopy they appear to be small lipid-containing cytosomes,<sup>459</sup> the origin of which is not known. Moderate thrombocytopenia also may occur.

Serum lipids usually are normal, but, in some of the patients, cholesterol and phospholipids may be increased.<sup>440</sup>

**DIAGNOSIS.** The clinical picture plus the demonstration of the characteristic foamy cells filled with lipid (Fig. 42-9), which are found in the bone marrow or spleen, are usually sufficient for diagnosis. Measurement

of sphingomyelinase activity in leukocytes, cultured skin fibroblasts, or other tissues<sup>341,347</sup> has proved useful in prenatal diagnosis<sup>347</sup> and in detecting heterozygotes.<sup>347</sup>

**PROGNOSIS AND TREATMENT.** In general, Niemann-Pick disease runs a much more rapid course than does Gaucher's disease. Most patients die within a few months, after a period of severe general deterioration. However, a few have lived to 20 years of age.<sup>410,443</sup>

Treatment is necessarily symptomatic and supportive. Infections are treated as they arise. Splenectomy has been of little value except to relieve symptoms caused by the massive size of the spleen.

### Sea-Blue Histiocytosis

**HISTORY AND PATHOGENESIS.** The term "sea-blue histiocyte syndrome" was coined in 1970 to describe a clinical picture consisting of splenomegaly, mild purpura secondary to thrombocytopenia, and, occasionally, hepatic cirrhosis associated with the presence of numerous histiocytes in the spleen and bone marrow which stain a sea-blue color (Plate II, F, p. 72).<sup>491</sup> The first patient to be reported was a 27 year old man with splenomegaly, numerous blue-pigmented macrophages in the marrow, and a white ring in the macular area of the optic fundi.<sup>490</sup> He has survived with no progression of his disease. Since the next report, in 1954,<sup>495</sup> more than 20 cases have been described.<sup>470,471,476,485,487,490,493</sup> Reports of single cases have predominated, but the disorder has been seen in siblings<sup>471,487</sup> and sea-blue histiocytes were found in four members of one family—the father, mother, and two children.<sup>487,490</sup> Consanguinity was prominent in this family. The disease appears to be panethnic since patients have been reported from America, Europe, Puerto Rico, and Iran<sup>482</sup> and cases have been described in individuals of Caucasian and Negro as well as of mixed ancestry.<sup>487</sup> The frequent occurrence in Puerto Ricans is unexplained. Inheritance is thought to be autosomal recessive.<sup>487</sup>

Tissue lipid analyses in a few patients have shown an increase in phospholipid, sphingomyelin, and total lipid in the spleen and bone marrow.<sup>487</sup> Histochemical studies have shown the presence of lipids containing cerebroside and carbohydrate within histiocytes.<sup>470,478,487,490</sup> In a few patients, increased urinary excretion of mucopolysaccharide was noted, but in others this has not been found.<sup>487</sup> No enzymatic defect has been suggested as a probable cause in this disorder, but low sphingomyelinase activity in the spleen has been reported in one or two patients. The source of the lipid in the storage cells is unknown.

**CLINICAL PICTURE AND COURSE.** Sea-blue histiocytosis may be manifested as a *primary familial syndrome*; or lipid-containing, sea-blue histiocytes may be found in patients with idiopathic thrombocytopenic purpura, chronic myelocytic leukemia, hyperlipoproteinemia, or other associated illnesses, so-called *acquired or secondary sea-blue histiocytosis* (see below):

Considerable variation in the clinical presentation of the *primary* form has been noted. Patients with this disorder usually seek medical attention because of hepatosplenomegaly. The age of detection has ranged from infancy to old age, but most patients have been younger than 40 years old when the diagnosis was made.<sup>490</sup> Macular abnormalities, skin pigmentation, or neurologic manifestations have been reported in only a few. Lung infiltrates suggesting tuberculosis or sarcoidosis have been described in about a third of the patients. Lymphadenopathy is unusual. Purpura is common. Thrombocytopenia is a nearly universal finding. Splenectomy has been carried out to alleviate this condition without apparent exacerbation of the general course.

In most patients the course has been benign and uncomplicated, but in a few there has been progression of disease to involve the bones, lungs, or liver. Death due to hepatic failure or pulmonary disease has been reported and massive gastrointestinal bleeding has occurred.<sup>487</sup>

In general, the younger the age at diagnosis the poorer the prognosis.

**DIAGNOSIS AND PATHOLOGY.** All patients with the primary disorder have numerous sea-blue histiocytes diffusely infiltrating the bone marrow. In most of them, these cells have been found in the spleen and the liver. Diffuse and widespread infiltration of the splenic white pulp is usually noted, but may be absent in older patients.<sup>487</sup> No consistent pattern is found in the liver or lymph nodes. Lipid histiocytes have also been found in the lungs in about one third of the patients.

The typical sea-blue histiocyte (Plate II, F) is a large reticuloendothelial cell of 20 to 60  $\mu\text{m}$  diameter with a single eccentric nucleus containing block chromatin and a single nucleolus. When stained with Wright's or Giemsa stain the cytoplasm is seen to contain sea-blue or blue-green granules in varying numbers. Histochemically the granules stain with Sudan black B, other lipid stains, PAS, and acid-fast stains<sup>478,487</sup> and exhibit autofluorescence.<sup>466,478</sup> Electron microscopy reveals lamellae of lipid molecules with a characteristic periodicity.<sup>478,487</sup>

**ACQUIRED OR SECONDARY SEA-BLUE HISTIOCYTOSIS.** Although the familial occurrence and the clinical picture just described suggest the existence of a syndrome secondary to an as yet undefined metabolic defect, sea-blue histiocytes are not specific for this disorder.<sup>480,486</sup>

In a few patients with idiopathic thrombocytopenic purpura, similar if not identical cells have been found in the spleen,<sup>463,474,484</sup> but their presence in the bone marrow has been noted in only one patient.<sup>480</sup> In one study, lipid histiocytes were found in six of 737 spleens removed for various causes.<sup>484</sup> All six patients had thrombocytopenic purpura. Curiously the characteristic cells were not found in the spleens of patients splenectomized before 1953. This led to the suggestion that the sea-blue histiocytes might be related to the therapeutic use of adrenal corticosteroids, but in patients with the disease who were not so treated such cells also have been reported.<sup>484</sup> No association with the

duration of the thrombocytopenia, age of the patient, or other clinical parameters could be established.<sup>466,481</sup> In another study, when autofluorescence was used as a means of detecting lipid-laden histiocytes, these cells could be demonstrated in more than half the patients splenectomized because of ITP.<sup>466</sup> An arrangement of histiocytes around the periphery of the malpighian bodies is said to be a characteristic in patients with ITP.<sup>466</sup> Electron microscopy revealed numerous myelin figures and platelets in various stages of degeneration in the histiocytes found in spleens removed from eight of nine patients with ITP.<sup>468</sup>

Sea-blue histiocytes have been identified also in the spleens of occasional patients with thalassemia (Chapter 26, page 859), chronic myelocytic leukemia,<sup>378</sup> polycythemia vera, sickle cell anemia, sarcoidosis, chronic granulomatous disease,<sup>473</sup> lipochrome histiocytosis, hyperlipoproteinemia, Wolman's disease, hereditary acyltransferase deficiency, or various lipidoses.<sup>480,483,490</sup> We have seen them in a patient with multiple myeloma.

It is not yet clear whether secondary sea-blue histiocytosis is the result of overloading of normal enzyme systems or is due to a mild enzymatic deficiency.

### Fabry's Disease (Angiokeratoma Corporis Diffusum Universale)

**HISTORY AND DEFINITION.** This disorder was first described by Fabry<sup>516</sup> and by Anderson<sup>500</sup> in 1898 as a peculiar nodular, purpura-like skin lesion. Over the next 25 years, several more cases were reported.<sup>517</sup> Ultimately the condition emerged as a clinical syndrome characterized by skin lesions, usually distributed over the scrotum, ilio-sacral region, thighs, and around the umbilicus, occurring in males only, which is also usually associated with albuminuria and edema of the lower extremities or around the eyes. Pain, cramps, numbness, and flushing of the extremities in warm weather and cardiac enlargement also were noted in the affected men. Microscopic sections of the skin lesions revealed dilated vascular channels in the epi-

thelium often with a hypertrophic stratum corneum overlying them. A familial occurrence was noted and thickening of the media of medium-sized and large arteries, especially prominent in the kidneys, with vacuolization of smooth muscle fibers in vessel walls and the myocardium and accumulation of hyaline material therein was described.<sup>534,536</sup> Thus the systemic nature of the disorder was established and a metabolic defect, perhaps a thesaurismosis, was postulated.<sup>534</sup> The nature of the stored material was not identified until the early 1950's when the phospholipid nature of the birefringent deposits was recognized.<sup>517</sup> Fessas and associates, in 1955, were the first to report the disorder in an American patient, who was referred to them because of "purpura" (Fig. 42-10A), anemia, and albuminuria. Intracellular birefringent bodies were demonstrated in this patient's urine and "foam" cells were found in his bone marrow (Fig. 42-10C, D).<sup>517</sup> Studies of an English family demonstrated the typical renal lesion in females as well as males,<sup>512</sup> a finding subsequently confirmed.<sup>533</sup> By 1961 about 35 cases had been reported and the pattern of inheritance was shown to be sex-linked recessive.<sup>529,532,535</sup> In 1967 the enzymatic defect was established as ceramide trihexosidase or  $\alpha$ -galactosidase deficiency (Fig. 42-6A).<sup>507</sup> Cultures of skin fibroblasts from a patient's mother and sister demonstrated two distinct clonal populations, one with and one without enzymatic activity.<sup>537</sup> This provided evidence of gene inactivation (Lyonization) in female carriers, whose intermediate levels of 15 to 40% of normal enzymatic activity<sup>521</sup> probably explain the usually mild nature of the disease in the female. It is not yet clear whether the X-linked defect is in a structural or regulator gene.<sup>505</sup> The fact that plasma infusions from normal subjects lead in several hours to an increase in plasma ceramide trihexosidase activity to over 150% of normal in patients with Fabry's disease suggests that the defect may be in a regulator gene.<sup>505,523,528</sup>

**ETIOLOGY, PATHOLOGY, AND PATHOGENESIS.** The deficiency in  $\alpha$ -galactosidase<sup>505,507</sup>

leads to accumulation of ceramide trihexose in many cells, especially smooth muscle cells in the walls of the blood vessels, in cardiac muscle, and in renal epithelium, as well as in bronchial epithelium, neurons, histiocytes, and endothelium throughout the body.<sup>501,512,519-534</sup> These deposits can be seen following PAS or sudan black B staining of vessel endothelial cells, histiocytes, or smooth muscle cells.<sup>519</sup> Under the electron microscope, myelin figures with a periodic structure similar to that found in some of the other lipidoses are seen.<sup>519</sup> However, the source of the cerebroside is not at all clear and the tissue distribution is quite different from that seen in the other lipidoses. The absence of associated amino acids and plasma proteins in vessel walls has been thought to rule out the possibility of plasma lipoprotein as a source.<sup>525</sup> An apparent increase in pinocytotic activity suggests that glycolipid is taken up from surrounding tissue fluids. The increased blood and urine ceramide trihexose levels ( $10 \times$  normal) are compatible with this thesis. However, the lack of membranes surrounding many of the inclusions in endothelial cells and fibrocytes is not compatible, unless one postulates secondary rupture of phagolysosomes with liberation of incompletely degraded contents into the cell cytoplasm.<sup>530</sup> Since globosides are normally present in blood cells and kidney parenchyma while gangliosides are major constituents of neural tissue, and since there are no lipid deposits in neural cells, it has been suggested that Fabry's disease results from a block in globoside degradation.<sup>526</sup> According to this concept the CNS changes are secondary to deposits and changes in the blood vessels.

**CLINICAL PICTURE AND COURSE.**<sup>539</sup> The main features of the clinical picture were mentioned above. The course can be divided into three phases.<sup>535</sup>

The *childhood or adolescent phase* is characterized by crises of fever, burning discomfort of the hands and feet, paresthesias, proteinuria, and the appearance of the typical vascular lesions in the conjunctival vessels,

**Fig 42.10** A, Typical skin lesions on the buttocks of a patient with Fabry's disease. B, Subepidermal vascular aneurysm from skin of the patient shown in A. (Magnification approximately  $\times 200$ ) C, Vacuolated macrophage in bone marrow aspirate. D, Vacuolated cell in urinary sediment. (From Fessas, Wintrobe, and Cartwright,<sup>517</sup> courtesy of the authors and the American Medical Association.)

lips, and skin. These manifestations occur only in males. The crises of fever are commonly associated with limb pains and are precipitated by hot or cold weather. The pain is mainly in the skin of the fingers and toes and does not usually spread proximally. Episodes may be brief or last for several weeks. In some subjects the pain has been of such severity that suicide has been attempted because of it.

The skin lesions are not usually a source of complaint, but they are of paramount importance in diagnosis. They are punctate, blood-filled angiectasias and form in the superficial layers of the skin (Fig. 42-10A, B). They are dark red to almost black in color and their surface is shiny. Their blood content can be only partially expressed by compression, and minimal bleeding follows trauma or pricking with a pin. These lesions characteristically occur in clusters especially over the scrotum, around the umbilicus, and over the thighs and buttocks. As the disease progresses they become more numerous and more extensive in distribution. The disease (or variants thereof) may occur without skin lesions<sup>509</sup>; this is the usual pattern in females, but may be encountered in males as well. The venules in the conjunctivae and the fundus oculi show tortuosity, dilatation, and sacculatation and corneal opacities are seen on careful slit-lamp examination.<sup>535</sup> Some edema is present in most affected males, and proteinuria is common. Vacuolated macrophages may be seen in the urine (Fig. 42-10D).<sup>517</sup> Anhidrosis may be noted in some patients and presumably explains the discomfort experienced by them in hot weather or after exertion.

During the *quiescent phase*, which is observed in early adult life, the crises cease, but proteinuria, cylindruria, and deterioration of renal function continue and anhidrosis becomes more prominent. The skin lesions increase in number.

The accelerated phase develops in adult life and is characterized by progressive renal failure, hypertension, cardiomegaly, and finally death in the fourth or fifth decade of life,

usually from renal failure or vascular accidents.

Cerebral symptoms and even cerebral vascular occlusions or myocardial infarctions may occur in a young patient, and varicose veins and hemorrhoids are common. Although pulmonary symptoms have been attributed to Fabry's disease there is little evidence to support this claim.<sup>503</sup>

In the heterozygous females, clinical manifestations are lacking.

**LABORATORY FINDINGS.** A moderate degree of anemia is common. It is usually hypochromic and possibly results from the bleeding hemorrhoids, but it may be normochromic and normocytic.<sup>519</sup> The findings in the bone marrow and urine have been mentioned already.

**DIAGNOSIS.** The clinical picture is so characteristic that in male subjects the diagnosis of Fabry's disease can usually be made if this disease is thought of. The skin lesions, however, have been mistaken for purpura. The diagnosis can readily be confirmed by chemical analysis of plasma<sup>547</sup> or of urinary sediment for the abnormal sphingolipid. Heterozygous carriers also can be detected by these means.<sup>514</sup> Tissue cultures can be assessed for accumulation of the poorly catabolized lipid, or the level of the enzyme ceramide trihexosidase can be measured.<sup>547,507</sup> Specific enzyme assay should probably be used since variants occur.<sup>509</sup>

**TREATMENT.** No treatment has been devised to prevent the development and progression of Fabry's disease. Infusions of normal plasma have produced transient increases in serum ceramide trihexosidase activity and decreases in serum ceramide trihexose levels,<sup>523,529</sup> but no long-term improvement has resulted. A few uremic patients have received renal allotransplants with some benefit, but whether or not the transplanted kidney can correct the basic metabolic defect is moot.<sup>510,533</sup>

As with many of the other lipoidoses, amniotic fluid cell analysis permits identification of an affected, hemizygous fetus.<sup>547</sup>

## Histiocytosis X

### Introduction and History<sup>592,619</sup>

The clinical triad of defects in membranous bone, exophthalmos, and polyuria in children, subsequently known as *Hand-Schüller-Christian disease*, was outlined in 1921 in a review by Hand.<sup>575</sup> In this review, Hand described the first six cases, including those of Christian and of Schuller and his own first case reported in 1893.<sup>574</sup> All six patients had hepatosplenomegaly, lymphadenopathy, and bone lesions, but not all had exophthalmos and polyuria. Attempts to link the disorder to xanthoma tuberosum, lipid storage disease,<sup>605</sup> and the xanthomatoses<sup>616</sup> proved unsuccessful and to this day there is no evidence that a specific biochemical defect is responsible for the condition. However, the "foamy" or "xanthoma" cell came to be regarded as a pathognomonic feature of the syndrome.<sup>592</sup>

A rather different clinical entity, consisting of fever, bilateral otitis media, hepatosplenomegaly, and adenopathy in a young infant who soon died was described by Letterer in 1924.<sup>588</sup> In 1933, Siwe described a condition in a 16 month old girl who died after a three-month illness during which she had fever, hepatosplenomegaly, lymphadenopathy, neutrophilia, and a destructive bone lesion in a fibula.<sup>611</sup> At autopsy, massive infiltrates of large cells resembling histiocytes were found. Siwe reviewed five other cases from the literature (including that of Letterer) and concluded that they constituted a single clinical entity.

In 1940, two groups of investigators<sup>591,602</sup> called attention to a syndrome in which there was infiltration of bone by eosinophilic granulomas. Several years later, Farber and co-workers<sup>564,573</sup> described a group of patients with solitary *eosinophilic granuloma of bone* the lesions of which usually healed promptly after irradiation or curettage. These authors concluded that their cases fitted a spectrum of disease, including Letterer-Siwe and the Hand-Schüller-Christian syndrome. In 1953,

because of the similarity of the histiocytosis observed in these three disorders, Lichtenstein<sup>577,590</sup> grouped them under a single heading which he designated "histiocytosis X" to indicate their unknown cause. At first well received,<sup>546,584,595</sup> this unifying concept has been contested by some workers<sup>601,612</sup> and has lost favor.<sup>592,612</sup> The cause of these conditions is still unknown.

### Eosinophilic Granuloma

Unifocal or multifocal granulomas, which on pathologic section exhibit a mixture of histiocytes and mature eosinophils, are the distinguishing features of eosinophilic granuloma, the most common of the three entities under consideration.<sup>547,592</sup> In one study of 82 patients with the three syndromes, 74 were noted to have eosinophilic granuloma. Of these, 50 had unifocal and 24 multifocal granulomas.<sup>592</sup>

#### Unifocal Eosinophilic Granuloma of Bone

These lesions have been observed in patients of all ages (16 months to 61 years). Of the 50 patients mentioned above, 27 were children under the age of 10 years and in all but six the disease occurred before the subjects were 40 years old.<sup>592</sup> Males were affected more commonly than females (ratio 3:2). Lesions were found in many different bones, but the head, ribs, and femurs were the most common sites (Table 42-3). The ribs were most frequently affected in adults, while the head and femurs were the usual locations in children.

The clinical picture and course of the disease are characterized by pain, tenderness and sometimes swelling over the affected bony site. X-ray examination reveals rarefaction in the medullary areas of the membranous or long bones. As the lesion enlarges it erodes the inner table of the cortex and resembles a cyst (Fig. 42-11). In some of the patients, reactive sclerosis may develop. Pathologic fracture and vertebral collapse may occur. Occasional cases may mimic sarcoma of

**Table 42-3. Sites of Lesions in Unifocal Eosinophilic Granuloma of Bone<sup>592</sup>**

Site	< 15 Years	> 15 Years	Total
Head	7	3	10
Scapula	1	1	2
Clavicle	1	1	2
Humerus	2	1	3
Radius	1	—	1

Ribs	1	9	10
Ilium	5	—	5
Pubis	2	—	2
Femur	9	2	11
Tibia	2	—	2

bone.<sup>519</sup> Generally there are few if any constitutional symptoms and in a series of 50 patients none exhibited exophthalmos or symptoms of diabetes insipidus.<sup>592</sup>

There are no helpful laboratory findings and there is no associated blood eosinophilia. *Diagnosis* is made by means of biopsy. Simultaneous curettage often suffices as treatment for these solitary lesions.<sup>599</sup> Modest doses of x-ray therapy (500 to 1500 rads) also have been reported to be helpful, while some lesions heal without therapy.<sup>599</sup> Radiotherapy is the *treatment* of choice when the lesions involve vital areas such as the neck of the femur, ramus of the mandible, or vertebral bodies and areas such as orbital lesions where good cosmetic results are important. In such cases, low dosage (300 to 600 rads) is recommended.<sup>599</sup>

#### *Unifocal Eosinophilic Granuloma in Sites Other Than Bone*

Solitary lesions characterized by granuloma formation with marked eosinophilic infiltration have been reported in tissues other than bone, especially the lungs and the gastrointestinal tract. Extraordinarily rare sites of involvement are the thymus, urinary bladder, parotid gland,<sup>550</sup> hypothalamus,<sup>551</sup> and skin.<sup>597</sup> In the gastrointestinal tract, solitary lesions may simulate polyps, gastric carcinoma, or gastric or duodenal ulcer.<sup>607</sup>

*Unifocal pulmonary eosinophilic granuloma* appears predominantly in young white males.<sup>553,617,622,624</sup> The onset is usually sudden and symptoms consist of cough, weight loss, and dyspnea. Some patients are asymptomatic and their disease then is detected only by x-ray examination, which reveals discrete or coalescent nodular infiltrates and small cystic areas. Lung biopsy is required for diagnosis. Electron microscopy has revealed peculiar rods in some lesions.<sup>571</sup> The acute phase of the disease usually subsides spontaneously after a few months, leaving residual interstitial fibrosis. Spontaneous pneumothorax occurs in 20 to 50% of the patients.<sup>622</sup>

**Fig 42-11.** Radiolucent eosinophilic granuloma of humeral diaphysis with periosteal reaction. Ewing's tumor was a differential diagnostic problem. (From Ochsenr,<sup>599</sup> courtesy of the author and Charles C Thomas.)

Fig 42-12. Osteolytic lesions in the skull of a patient (D E J) with Letterer-Siwe disease

Adrenocorticosteroid or x-ray therapy has been reported to be of some therapeutic benefit.<sup>553</sup>

#### *Multifocal Eosinophilic Granulomas of Bone and Schüller-Christian Disease*

Patients of all ages (1 month to 57 years) may be affected with multiple eosinophilic granulomas, but most, 22 out of 24 in one series<sup>592</sup> and 18 of 29 in another,<sup>547</sup> developed symptoms before the age of five years. Males predominate to some degree.<sup>547,592</sup>

If a patient with unifocal disease is going to develop additional lesions this usually occurs within six months of the finding of the first lesion.<sup>592</sup> The classic clinical picture of Hand-Schüller-Christian disease, namely, exophthalmos, diabetes insipidus, and bone lesions, was seen in only six of 24 patients with multifocal disease,<sup>592</sup> but symptoms either of diabetes insipidus or of exophthalmos were somewhat more common, being seen in one third to one half of the patients.<sup>547,592</sup> When

carefully sought, pituitary dysfunction is found in most patients.<sup>556</sup> Lymphadenopathy, splenomegaly, or hepatomegaly is present in 25 to 50% of the patients, as is dermatitis. Most develop fever during the acute phases of the illness. The disease is chronic in course, however, and usually begins with a *chronic otitis media*. Other modes of presentation include polydipsia and polyuria (diabetes insipidus), together with increasing irritability, exophthalmos, extrusion of teeth in association with bone lesions in the jaw, and even dermatitis.

*Defects in membranous bones* are manifested chiefly by sharply defined lesions in the skull, which often assume a geographic pattern (Fig. 42-12). The face may be deformed by involvement of the bones of the orbit. Erosions of the mandible are relatively common, usually the tooth-bearing portions, and ultimately displacement of the teeth by the tumor causes them to appear in roentgenograms as if suspended in space. Involvement of the mastoid bone in association with the

chronic otitis media is also very common. Other bones that may be involved include the pelvis, femurs,<sup>592-598</sup> ribs, humerus, and spine.<sup>547</sup> In the *long bones* the lesions occur toward the ends of the shafts. There is thinning from within and, in contrast to the lesions in membranous bone, periosteal reaction often occurs.<sup>547</sup> *Exophthalmos* develops as a consequence of orbital tumors. Symptoms of *diabetes insipidus* are presumably due to involvement of the pituitary gland or hypothalamus; associated destruction of the sella turcica is infrequent.

*Skin and mucous membrane* lesions include ulcerations that resemble those seen in the Letterer-Siwe syndrome<sup>625</sup> or xanthoma disseminatum. Those resembling xanthoma disseminatum consist of painless, yellowish-brown, maculopapular lesions that may be scattered over the face, especially the eyes and mouth, trunk, perineum, and axillae. Fibrotic lesions associated with extracellular lipid deposits (presumably late-stage healing lesions) may be found in the mouth, under the tongue, and in the pharynx and larynx.<sup>581</sup>

Involvement of the *lungs* may be perihilar, central, or diffuse. Bilateral interstitial pulmonary infiltration leads eventually to fibrosis,<sup>603</sup> honey-combing of the lungs, and episodes of spontaneous pneumothorax; the course is variable,<sup>589</sup> but alveolocapillary block, cor pulmonale, and right heart failure may develop. Pleural involvement is unusual.

Moderate enlargement of the *liver, spleen, and lymph nodes* may occur. Gastrointestinal lesions can simulate ulceration of the stomach or duodenum, or polyps or carcinoma.<sup>607-613</sup> Actual involvement of the nervous system is rare<sup>547-561</sup> except for the hypothalamus.

Anemia may or may not be found. When it occurs it is of the non-regenerative type<sup>578</sup> and may be accompanied by leukopenia or thrombocytopenia. Rarely myelophthisic anemia may be noted. In one subject,  $\gamma$ -paraproteinemia was observed and led to a mistaken diagnosis of multiple myeloma.<sup>582</sup>

*Diagnosis* may be difficult to establish unless a characteristic combination of signs is present. Outstanding features in various

combinations and with or without signs of wasting disease are: skeletal lesions; cutaneous, oral, or anogenital manifestations; hepatosplenomegaly; adenopathy; exophthalmos; and diabetes insipidus. A bone lesion may develop so rapidly and break through the cortex so readily that prior to biopsy it may be mistaken for a malignant tumor, such as Ewing's sarcoma. Multiple foci may suggest metastatic neuroblastoma. Chronic otitis media, intractable seborrhea, or milium pulmonary infiltrates also may lead one astray. The diagnosis ultimately rests on histologic examination of involved tissue.

*Pathologically*, lesions such as those in the skull are found to consist of defects, of various shapes and size, which are filled with a light yellow or brownish, tough substance. Similar granulation tissue is found in the spleen, liver, lymph nodes, and other tissues. The basic microscopic picture of the bone lesions, whether uni- or multifocal, is that of a mixture of mature eosinophilic leukocytes and histiocytes in varying proportions.<sup>592</sup> The histiocytes may or may not contain considerable phagocytized cellular debris. In many specimens the mononuclear cells vary in size, contain abundant cytoplasm, and may take on a syncytial appearance. Mitotic figures are unusual; occasional giant, multinucleated histiocytes are seen. It is uncommon to find more than an occasional foam cell or xanthoma cell in the bone lesions. Such cells are present primarily when there has been *chronic suppuration (as in chronic mastoiditis)* in which case they are found interspersed among fibroblasts.<sup>592</sup> Ultimately there is a decrease in the number of eosinophils and a tendency to healing and fibrosis. If one searches carefully, Charcot-Leyden crystals may be demonstrable.<sup>549</sup>

The skin lesions of eosinophilic granuloma may have the characteristic appearance of eosinophilic granuloma, or an almost purely histiocytic reaction may be noted. In the latter case it is difficult to make the diagnosis and confusion readily occurs with the lesions seen in the more malignant Letterer-Siwe disease.<sup>592</sup>

The ultimate prognosis is better<sup>547,592</sup> than once was thought.<sup>613</sup> The outlook may be less good when the condition begins early in life<sup>584</sup> and death may result from pulmonary fibrosis, pneumothorax, or other causes. However, spontaneous modest improvement or even remissions have been observed. Thus in one series of 29 cases, one third of the patients recovered, one half continued to have active disease, and 13% died.<sup>547</sup> In a more recent series of 24 cases<sup>592</sup> only one patient died, of an unrelated cause. In general the prognosis can be related to the extent of the disease process, the number of tissues involved<sup>584</sup> and whether or not there is impairment of organ function.<sup>586</sup>

As these syndromes have been studied more carefully, it has become apparent that a child with a solitary "eosinophilic granuloma of bone" may develop signs suggesting systemic disease, and similar lesions may be found in extra-skeletal sites such as lymph nodes, skin, oral cavity, lungs, or the anogenital region. However, the transition from solitary to multifocal lesions appears to occur in less than half of the cases.<sup>592</sup>

**TREATMENT.** As already mentioned, spontaneous healing of lesions may occur and simple curettage or small doses of x-ray therapy given to localized lesions<sup>599</sup> may induce a favorable response. Systemic therapy with methotrexate, vinca alkaloids, corticotropin,<sup>565</sup> adrenal steroids,<sup>548</sup> cyclophosphamide, or nitrogen mustard is usually advised to control the widespread lesions.<sup>585,592</sup> Adrenal corticosteroid therapy is capable of reversing all the skeletal and visceral manifestations when large doses (2 to 4 mg of prednisone per kg of body weight per day) are administered for six- to eight-week periods. With such therapy, remissions were obtained and sustained for 12 to 30 months.<sup>548</sup> Vinblastine sulfate in doses of 0.2 to 0.3 mg/kg given weekly has also been effective<sup>610</sup> as is vincristine (2 mg/m<sup>2</sup> weekly) or cyclophosphamide given orally (5 mg/kg per day).<sup>614</sup> With these forms of therapy complete remissions, perhaps cures, have

been achieved in 20 to 50% of the patients and partial remission in an additional 50 to 60%.<sup>614</sup>

**PATHOGENESIS.** Most students of this disorder regard it as an inflammatory granuloma, possibly of infectious origin, rather than a metabolic disorder as once assumed. Electron microscopic studies have failed to demonstrate virus particles,<sup>604</sup> but lysosomes, myelin figures, and endoplasmic reticulum are prominent throughout the cytoplasm of the histiocytes.<sup>604</sup> There is no evidence of consanguinity in the families of affected patients.<sup>566</sup>

### *Letterer-Siwe Disease*

The term "Letterer-Siwe disease," as originally used, described an acute illness of unknown cause<sup>545</sup> characterized by: (1) occurrence in infants exclusively, (2) marked splenomegaly, considerable hepatomegaly, lymphadenopathy, (3) localized bone tumors, often with erosion demonstrable by x ray, (4) anemia with normal or decreased platelets, unremarkable leukocyte differential count, a hemorrhagic diathesis, and (5) increased numbers of nonlipid histiocytic cells in splenic aspirates. Subsequent studies have modified these criteria.

Letterer-Siwe disease occurs less frequently than does solitary or multifocal eosinophilic granuloma. It has been observed in young children as well as infants, and occasional cases have been reported in older children.<sup>547,584,592</sup> A few cases have been described in neonates.<sup>560</sup>

**CLINICAL PICTURE.** There is evidence of a wasting disorder with enlargement of the spleen, liver, and lymph nodes. Moderate fever is often present. Exophthalmos and diabetes insipidus are less prominent in this disorder than in Schüller-Christian disease,<sup>592</sup> but all patients have had skull lesions like those described in that condition. *Bone lesions* occur in many other sites as well, the upper extremities being commonly affected.<sup>562</sup> *Skin* involvement is particularly

Fig 42-13. The typical rash of Letterer-Siwe disease—papular, scaly, crusted lesions predominantly on the trunk with confluent erythematous lesions in the groin (From Lahey<sup>585</sup> courtesy of the author and Harper & Row)

prominent in Letterer-Siwe disease (Fig. 42-13) and not infrequently is the presenting complaint.<sup>625</sup> The lesions are papular, scaly and crusted and are seen predominantly on the trunk and over the scalp; they may ulcerate or, on occasion, become hemorrhagic. *Lymphadenopathy* appears to result from direct histiocytic infiltration rather than due to secondary involvement from more distal lesions.<sup>564</sup>

**LABORATORY FINDINGS.** Anemia is common in this syndrome, thrombocytopenia is frequent, leukopenia may occur, and pancytopenia has been reported.<sup>594</sup> The anemia is normochromic normocytic and is often hemolytic.<sup>565</sup> The pathogenesis of the thrombocytopenia is not clear, there being no good correlation with the degree of marrow involvement or the number of megakaryocytes in the bone marrow.<sup>562</sup> Monocytosis may occur.<sup>585</sup> Hemohistiocytes have been seen in the blood<sup>600</sup> and a leukemic picture has been observed.<sup>567,585</sup>

**DIAGNOSIS.** Widespread involvement of bone, skin, and the reticuloendothelial system in infants, with histiocytic infiltration demon-

strable on biopsy, establishes the diagnosis. However, when involvement is in atypical sites or is less extensive than usual, confusion concerning the diagnosis may arise. Thus the skin lesions may be mistaken for seborrheic dermatitis; the bone lesions may be confused with neoplasms or osteomyelitis; and the lung infiltrates may be mistaken for those due to tuberculosis, histoplasmosis, or cystic fibrosis. Spleen puncture is useful mainly in ruling out the possibility of lipid storage diseases,<sup>619</sup> but skin biopsy may be misleading.<sup>592</sup>

**PATHOLOGY.** The pathologic picture of Letterer-Siwe disease has not been clearly delineated and there is considerable overlap between the lesions in this condition and those of multifocal eosinophilic granuloma.<sup>592</sup> In the latter, there is a mixture of eosinophils and histiocytes with indistinct cell membranes forming sheets with a polygonal shape, which produce a syncytial appearance.<sup>586</sup> In contrast, in Letterer-Siwe disease there is diffuse infiltration by cells with abundant cytoplasm and distinct cell membranes, together with rare giant cells,

eosinophils, or fibrosis. There is no tendency to develop a syncytial appearance.<sup>586</sup>

**PROGNOSIS, COURSE, AND TREATMENT.** Depending on the type of cases included under this category, whether only acute cases or also the more chronic ones, Letterer-Siwe disease has been regarded as uniformly fatal<sup>545,592</sup> or the prognosis has been considerably better than had been thought in the past.<sup>594</sup> Mortality is low in patients with the least extensive disease and high when the disease is widely disseminated. Onset before the age of six months appears to carry a bad prognosis. The overall mortality in one series of 69 patients was 34%. No patient over three years of age at onset of the disease died during the course of that study.<sup>584</sup>

When the disease is widespread and extensive, treatment must be aggressive. The use of vincristine (2 mg/m<sup>2</sup> weekly) or vinblastine intravenously (6.5 mg/m<sup>2</sup> initially, with subsequent dosage modified according to toxic side effects), or of cyclophosphamide orally (5 mg/kg/day), resulted in complete remission in 20 to 50% of the patients in one series and partial remissions in 50%.<sup>611</sup> However, good results also have been reported in patients treated with antibiotics,<sup>554</sup> prednisone,<sup>548</sup> or a variety of other chemotherapeutic agents.<sup>585</sup>

**PATHOGENESIS.** Because of the rapidly fatal course, this syndrome is regarded by some as a neoplastic process.<sup>592,619</sup> However, the occasional response to antibiotics suggests an underlying infectious process.<sup>554</sup> The concentration of deaths in the first two years of life and the occurrence in siblings and in several sets of twins<sup>570,619</sup> as well as in neonates have been taken to indicate a prenatal origin, perhaps viral infection.<sup>570,619</sup>

Electron microscopy has revealed peculiar atypical granules in the histiocytes in this disorder,<sup>558,608</sup> but similar ones also have been found in normal skin and in other tumors.<sup>619</sup>

Several studies have suggested genetic inheritance.<sup>568,579</sup> The above-mentioned incidence in siblings and twins<sup>570</sup> indicates the

need for careful study of family members and of chromosome constitution.

## Infectious Mononucleosis

History and Terminology  
Etiology  
Epidemiology  
Clinical Manifestations  
Complications  
Laboratory Findings  
Differential Diagnosis  
Treatment  
Prognosis  
Pathology

**I**NFECTIONOUS mononucleosis is an acute sporadic infection that usually affects young adults. It is accompanied by irregular fever, severe pharyngitis, adenopathy, and splenomegaly. Characteristic laboratory findings include an absolute lymphocytosis with many "atypical" cells, antibodies against heterologous red cells, and rising titers against the Epstein-Barr virus.

### History and Terminology

In the first decade of this century, several cases of glandular enlargement, sore throat, and mononuclear cell increase were described by Turk,<sup>280</sup> Cabot, Marchant, and others,<sup>295</sup> sometimes as examples of acute leukemia with apparent cure. It remained for Sprunt and associates<sup>290</sup> to classify these cases and six of their own under the title "*infectious*

*mononucleosis*" and to point out that blast-like cells of a peculiar type were present in the blood. A detailed morphologic description of these cells was later published by Downey and coworkers in 1923.<sup>68</sup>

An important advance was made in 1932 when Paul and associates discovered that the sera of patients with infectious mononucleosis contain antibodies against sheep erythrocytes in concentrations far above normal.<sup>221</sup> Equally important has been the more recent discovery of the association between infectious mononucleosis and the Epstein-Barr virus<sup>70,80,192</sup> (see below).

In many textbooks and articles it is still stated that infectious mononucleosis was first described by Pfeiffer<sup>226</sup> in 1889 as "Drüsenfieber," a "glandular fever" of epidemic nature, and that subsequently the condition was also reported by others.<sup>15,24,293</sup> Tidy and colleagues<sup>276</sup> suggested that glandular fever and infectious mononucleosis are one and the same. However, a careful analysis of clinical data by Hoagland<sup>143</sup> showed pronounced differences between these two conditions. *Glandular fever* is highly contagious, usually affects children, and is of short duration. The throat is only mildly inflamed and adenopathy may be restricted to the cervical nodes only. The spleen is not enlarged, except when the illness is very protracted. Thus, on clinical and epidemiologic grounds alone, infectious mononucleosis is clearly separable from Pfeiffer's Drüsenfieber (see below).

## Etiology

The search for an etiologic agent in infectious mononucleosis has exemplified Sherlock Holmes' dictum that "it is a capital mistake to theorize before one has data." Suspected etiologic agents have ranged from cocci and bacilli to spirochetes, protozoa, and viruses.<sup>295</sup> Most intriguing has been the association between sporadic, heterophil-positive infectious mononucleosis and a herpes-like agent, which was first described in 1964 by Epstein, Achong, and Barr as present in lymphoblasts cultured from patients with Burkitt's lymphoma<sup>79,80</sup> (see also page 1452). These findings were subsequently confirmed by others<sup>129,164</sup> and the agent is now commonly referred to as the Epstein-Barr virus (EBV). Although its association with Burkitt's lymphoma remains most firmly established, it has also been identified in lymphoid cell lines derived from patients with infectious mononucleosis,<sup>192</sup> patients with various lymphomas,<sup>22</sup> those with leukemia,<sup>10</sup> those with sarcoidosis,<sup>133</sup> and from persons presumably in good health.<sup>197</sup> Interestingly, the EB virus is readily observed in lymphoid cell cultures derived from these subjects, but it rarely is seen in fresh biopsy material; nevertheless, the sera of patients with Burkitt's lymphoma,<sup>129,132,170,263</sup> of those with carcinoma of the postnasal space,<sup>66,133,215</sup> and of those with infectious mononucleosis<sup>5,192,205,267</sup> contain large quantities of anti-EBV antibodies suggesting that the presence of the virus in *in vitro* culture systems is not just an artifact. However, a firm etiologic relationship between such conditions and the EBV has not yet been established.<sup>10,22,133</sup> Indeed, low titers of anti-EBV antibodies may be seen in well over half of all normal individuals in a worldwide distribution.<sup>129,132,181,192,206,223</sup>

The implication of the EB virus as the cause of infectious mononucleosis is the result of a chance observation made in 1967<sup>131</sup>. Blood taken from a laboratory technician who had contracted infectious mononucleosis led to the establishment of a lymphoid cell line containing the characteristic EB virus. Sig-

nificantly, previous attempts to establish a lymphoid cell line from this technician's blood had been unsuccessful and sera obtained prior to the onset of clinical infectious mononucleosis had shown anti-EBV titers of less than 1:10 and a negative heterophil response. Following the onset of infectious mononucleosis, anti-EBV and heterophil titers rose. On the basis of these provocative clues, Henle and associates studied sera of a number of students from Yale University, where a prospective study of infectious mononucleosis had been in progress for many years. In all instances of clinical infectious mononucleosis the anti-EBV and heterophil titers rose together from a negative baseline. Of even greater interest was the observation that the anti-EBV titer remained persistently elevated in contrast to the transient nature of the heterophil response.

Since then other reports have provided further sero-epidemiologic evidence for the role of EB virus in infectious mononucleosis.<sup>5,83,105,139,178,205,246,255</sup> This evidence may be summarized as follows: (1) Typical heterophil-positive infectious mononucleosis is almost always associated with a rise in the titer of antibodies to EBV-related antigens.<sup>5,125,136,205</sup> In heterophil-negative "mononucleosis" the response is variable, but more commonly negative.<sup>5,83,169</sup> Other viral infections are not characterized by anti-EBV antibodies.<sup>83,130</sup> Antibodies to EBV-related antigens include those against EB-viral capsid antigens (VCA)<sup>126,129</sup>; antibodies to EBV-determined cell membrane antigens<sup>164</sup> which are comparable to some tumor specific antigens (TSA) of virus-induced tumors (page 329); antibodies to the D component of the EBV-induced early antigen (EA) complex<sup>132a</sup>; complement-fixing antibodies to soluble and viral antigens<sup>103</sup>; and EBV-neutralizing antibodies.<sup>136</sup> These various antibodies arise at different rates and times with respect to the onset of the illness and persist for varying lengths of time. Thus anti-VCA antibodies rise early, reach peak titers within a week or two after the onset of the illness, and persist for years if not for life.<sup>136</sup> But, while the presence of anti-VCA

Fig 43-1 Age and sex of 82 patients with infectious mononucleosis at the Johns Hopkins Hospital. Males are indicated by hatched columns, females by open columns. All the patients were white.

antibodies is an excellent indicator of infection, immunity appears to be mediated by virus-neutralizing antibodies.<sup>135</sup> These antibodies appear later and rise at a slower rate; peak levels, which may persist for years or life, may not be reached until the sixth or seventh week.<sup>138</sup> Anti-ID (anti-EA) antibodies are only found in 70% of patients with infectious mononucleosis, probably because they appear later than the anti-VCA antibody and fail to persist.<sup>136</sup> (2) Typical heterophil-positive infectious mononucleosis only occurs in individuals without previous significant anti-EBV titers and never in those with pre-existing anti-EBV antibodies.<sup>83,139,205,216,285</sup> (3) When long-term lymphoblastoid cell cultures are successfully established, they almost *always* contain the EB virus, whether they have been derived from patients with Burkitt's lymphoma, infectious mononucleosis, or leukemia, or, under special circumstances, from healthy individuals.<sup>192</sup> The ease of establishing such cultures from persons with a recent or past history of infectious mononucleosis<sup>67,137,192</sup> contrasts markedly with the difficulty en-

countered with cells of individuals without such a history and has been used as evidence for the role of the EBV in infectious mononucleosis.<sup>192,267</sup> (4) The isolation of a virus from the throat washings of patients with infectious mononucleosis has been reported,<sup>115</sup> and filtrates of throat washings from these patients have been found to contain a herpes-like virus<sup>225</sup> that as yet has not been definitively identified. Such filtrates transformed cord blood lymphocytes.<sup>43,193,225</sup> However, transformation experiments must be viewed with some caution because the EBV viral genome was shown to persist in an EBV-negative cell line derived from a patient with Burkitt's lymphoma.<sup>127</sup> (5) The transmission of infectious mononucleosis by EBV-infected material or by purified virus would greatly strengthen the etiologic argument for the EB virus.<sup>267</sup> Two such instances of infectious mononucleosis transmission have been reported, but the details have not been published.<sup>115</sup> Transmission of EB virus infections through blood transfusions has been documented more frequently<sup>17,106,131</sup> and has sometimes been accompanied by typical clinical and laboratory manifestations of infectious mononucleosis.

In summary, there is strong evidence for the role of the EB virus in typical *heterophil-positive* infectious mononucleosis, although the etiologic relationship has not been established to the complete satisfaction of all workers.<sup>110,199,267</sup> *Heterophil-negative* infectious mononucleosis may be associated with EB virus infections,<sup>83,169</sup> especially in children,<sup>83</sup> but more commonly has been associated with cytomegalovirus infections.<sup>167,169</sup> Occasionally heterophil-negative infectious mononucleosis has been described in association with rising titers to herpes simplex and rubella viruses.<sup>285</sup>

### Epidemiology

**AGE.** Infectious mononucleosis occurs most frequently in young adults, the peak incidence being in persons between the ages of 17 and 25 years<sup>9,143</sup> (Fig. 43-1). The

**Table 43-1. Symptoms and Signs of Infectious Mononucleosis**

<i>Symptoms</i>	<i>%</i>	<i>Signs</i>	<i>%</i>
<i>Malaise and fatigue</i>	90-100	<i>Adenopathy</i>	100
<i>Sweats</i>	80-95	<i>Fever</i>	80-95
<i>Sore throat, dysphagia</i>	80-85	<i>Pharyngitis</i>	65-85
<i>Anorexia</i>	50-80	<i>Splenomegaly</i>	50-60
<i>Nausea</i>	50-70	<i>Bradycardia</i>	35-50
<i>Headache</i>	40-70	<i>Periorbital edema</i>	25-40
<i>Chills</i>	40-60	<i>Palatal enanthem</i>	25-35
<i>Cough (mild)</i>	30-50	<i>Liver or splenic tenderness</i>	15-30
<i>Myalgia</i>	12-30	<i>Hepatomegaly</i>	15-25
<i>Ocular muscle pain</i>	10-20	<i>Rhinitis</i>	10-25
<i>Chest pain</i>	5-20	<i>Jaundice</i>	5-10
<i>Arthralgia</i>	5-10	<i>Skin rash</i>	3-6
<i>Diarrhea or soft stools</i>	5-10	<i>Conjunctivitis</i>	5
<i>Photophobia</i>	5-10	<i>Pneumonitis</i>	3
<i>Abdominal pain</i>	5		
<i>Epistaxis</i>	3		

(From Finch <sup>90</sup> courtesy of the author and Blackwell Scientific Publications.)

disease is sufficiently uncommon in individuals beyond 30 years of age and so rare in those over 40 that the diagnosis in persons in the middle or late years should be made with special care, although it cannot be excluded on the basis of age alone.<sup>117,143,252</sup>

**SEX.** Statistics on sex distribution vary considerably,<sup>9,13,70</sup> but there is probably no sex predilection.<sup>12,143</sup>

**RACE.** While typical infectious mononucleosis is seen in American Negroes, the incidence of the disease appears to be lower than in Caucasians,<sup>126,143</sup> especially among army personnel; of 234 officers and enlisted men with infectious mononucleosis in Hoagland's series only 2 were black, while blacks constituted 12 to 14% of all army personnel.<sup>143</sup>

**SEASONAL INCIDENCE.** There is little evidence for a seasonal incidence,<sup>12,46,143</sup> but the disease appears to be most frequent after college vacations.<sup>12</sup> Epidemics are said to appear in the spring,<sup>15</sup> but Hoagland's careful analysis<sup>143</sup> suggested that, in most reported epidemics,<sup>193,208,276,292</sup> the diagnosis of infectious mononucleosis was not well established.

**MODE OF TRANSMISSION.** The contagiousness of infectious mononucleosis is

quite low and it is exceptional for members of a patient's family, roommates of the same sex, and other close associates to develop clinically obvious infection.<sup>12,46,143,210</sup> Nevertheless, the incidence of hematologic changes may be higher in contacts than in a control group,<sup>223</sup> and anti-EBV titers may rise in about 20% of susceptible contacts.<sup>210</sup> Most authorities agree that infectious mononucleosis is usually transmitted by the intimate oral exchange of saliva as occurs in kissing of more than filial intensity; it is sometimes transmitted by rapid, indirect oral means such as passing a bottle from mouth to mouth, and it is only rarely transmitted by blood transfusions.<sup>12,143</sup>

Clinical data suggest that acute infections are usually acquired from an infectious mononucleosis carrier: such carrier states have now been demonstrated.<sup>193</sup> Most infections are not acquired from a sick individual and subclinical mononucleosis, though frequently postulated, is uncommon.<sup>143</sup>

#### Clinical Manifestations (Table 43-1)

In the absence of a firmly established etiologic agent, various students of this disease in the past allowed themselves more or less liberty in its definition. Thus, many have held

Fig. 43-2. Usual frequency and duration of major symptoms in young adults with infectious mononucleosis (From Finch,<sup>90</sup> courtesy of the author and Blackwell Scientific Publications)

that the manifestations of infectious mononucleosis are protean<sup>15</sup> and that a great variety of disorders may be simulated by this condition. Some would make the diagnosis in the absence of a positive heterophil antibody response or even in the presence of only equivocal morphologic changes in the blood, basing their diagnosis on the presence of more or less typical clinical findings or even on little more than the lack of any better explanation for a self-limited febrile disorder in a young person. Others,<sup>110</sup> on the other hand, would restrict the diagnosis to patients in whom lymphocytes constitute more than 50% of the leukocytes, in whom "atypical" lymphocytes are present, and in whom both of these features have been present over a period of at least 10 days. When the diagnosis was restricted to patients displaying these laboratory features in addition to a heterophil antibody titer of at least 1:28 after guinea pig absorption, Hoagland found the clinical picture to be very consistent and not protean.

**SYMPTOMS** (Figure 43-2). The *incubation period* is uncertain and may be as long as 33 to 49 days.<sup>140</sup> In most young adults the symptoms are of fairly abrupt onset, although

close questioning will frequently elicit vague complaints of lassitude and ill-being for several days before the onset of more pronounced symptoms. Most of the early symptoms are nonspecific in nature. Excessive fatigue and general malaise may be accompanied by a sensation of feverishness, sweating, and chills; severe rigors almost never occur and the patterns of fever and perspiration are moderate and nonspecific.

*Anorexia* is a common early symptom. Its intensity and duration are often linked to the severity of sore throat and dysphagia. The anorexia frequently persists into the second and third week of illness. *Nausea* is equally common but vomiting is rare. Smokers often develop an acute distaste for cigarettes, and smoking may precipitate attacks of nausea. This may be one of the earliest symptoms of infectious mononucleosis. Other gastrointestinal complaints are rare, but some patients experience vague abdominal distress, including a peculiar sensation in the left upper quadrant when they are running, rolling over in bed, or are jarred. A small number of patients have several soft stools daily, but actual diarrhea is uncommon.

*Sore throat and dysphagia* are among the most important manifestations of infectious

mononucleosis and occur in 80 to 85% of all the patients; in some young adults, sore throat may be the only symptom of the disease. It usually develops gradually during the first week of illness and subsides during the second week. Occasionally sore throat returns later because of a superimposed beta hemolytic streptococcal infection. In the majority of patients the symptoms of pharyngitis are mild, but in some even taking sips of water may be painful. Rarely, massive tonsillar and pharyngeal edema may cause virtually complete pharyngeal obstruction.

*Headaches* occur early and usually subside during the first week; they may be retro-orbital in location. A few patients complain of photophobia and ocular muscle pain and some particularly observant individuals have complained of puffiness of the eyelids. Severe cough and chest pain are relatively rare symptoms, although mild cough is more commonly present. A few patients complain of myalgia, but the symptoms are usually mild and are confined to the neck and upper back.

**SIGNS (Fig. 43-3).** *Lymph node enlargement* is invariably present at some time and is bilateral<sup>140</sup>; the cervical glands were always enlarged in two large series of subjects.<sup>46,140</sup> Adenopathy increases rapidly during the first

week of illness, remains stationary during the second, and then slowly wanes. Anterior cervical enlargement is usually present. The posterior cervical nodes may be enlarged and are often palpable down to the clavicle,<sup>143</sup> but this finding is not pathognomonic of infectious mononucleosis. Enlargement of axillary and inguinal nodes is usually, but not invariably, present. Roentgenologically detectable hilar adenopathy is very rare (<1%) and is usually mild. Heat, redness or marked tenderness, fluctuation, and suppuration are conspicuous by their absence and militate against a diagnosis of infectious mononucleosis.

One would expect the *spleen* to be enlarged in all these patients, but the enlargement need not be palpable. Since splenomegaly has been looked for with varying degrees of diligence, it is difficult to be sure of the exact incidence of palpable enlargement. Nevertheless, during the second week of the illness the spleen is palpable in at least half to three quarters of all the patients.<sup>90,143</sup> Generally it extends 2 to 3 cm below the costal margin, but occasionally it may be larger and may even reach the iliac crest.<sup>15</sup>

Slight *hepatomegaly* is detected in 15 to 25% of patients with infectious mononucleosis. This may be accompanied by percussion tenderness over the liver and discomfort on

Fig. 43-3. Usual frequency and duration of major physical signs in young adults with infectious mononucleosis. (From Finch,<sup>90</sup> courtesy of the author and Blackwell Scientific Publications.)

palpation. The course of hepatomegaly closely follows that of adenopathy and splenomegaly. Jaundice may develop in about 10% of the patients and usually reaches its peak in the second week of the illness. Liver biopsy has shown varying degrees of sinusoidal infiltration, in rough agreement with functional tests<sup>162</sup> (see below).

The fever is of no characteristic type. It may be very transient and slight in degree, but in as many as one third of the patients it reaches a peak of 103° to 104°F.<sup>15,140</sup> This may occur at the end of four to eight days, the rise taking place in a remittent manner. A secondary rise after an initial drop to normal may accompany the onset of glandular swelling or sore throat. In one series of 196 cases, 11% of all the patients had no fever.<sup>46</sup> In another group of 200 cases, fever was present in all but five patients.<sup>140</sup> In the most seriously ill patient whom the authors have seen, a temperature of 106.6°F was reached following a chill and levels of 104°F were attained on three other days. This patient's throat was comparatively normal in appearance. The temperature curve may, occasionally, suggest malaria. In some instances it may suggest typhoid fever, especially since the pulse may be relatively slow.

*Pharyngeal inflammation* usually appears in the first week and then subsides rapidly. In about 25% of the patients, pharyngitis occurs first after the initial week of illness. It varies in intensity, but hyperplasia of the pharyngeal lymphoid tissue is almost always present. The palatal arch and uvula often have a gelatinous appearance, but significant edema of the uvula is unusual. Exudate, usually spotty, is seen in about a third of the patients.<sup>143</sup>

A *palatal exanthem*, consisting of 5 to 20 round, sharply defined, red spots at the junction of the soft and hard palates, is of great diagnostic, though not pathognomonic, value in infectious mononucleosis.<sup>140,143</sup> The spots occur in the second week of illness, turn brown within 48 hours, and disappear four to five days later.

*Edema of the eyelids*<sup>220</sup> has been described in a third of all subjects.<sup>140</sup> This consists of drooping of the swollen orbital portion of the

upper eyelids upon the palpebral portion and sagging of the latter. As a result the ocular aperture is narrowed.

A small number of patients develop a fine macular rash,<sup>70,143</sup> but in many the rash is probably due to drug allergy.<sup>143</sup> Indeed, several observers have noted that patients suffering from infectious mononucleosis were peculiarly prone to develop rashes when treated with ampicillin.<sup>21,228,246</sup> In one such study<sup>290</sup> the incidence of skin eruptions in the absence of antibiotics was 1%, with penicillin 3%, and with ampicillin 50%!

**COMPLICATIONS.** Physicians caring for large numbers of patients with infectious mononucleosis soon become impressed by the monotonous regularity with which the few basic signs and symptoms recur. Weird clinical patterns and serious complications are probably seen in no more than 1% of all patients.<sup>90,143</sup> Misconceptions about a higher incidence stem from the fact that most of the medical literature on infectious mononucleosis deals with complications and from impressions of sub-specialists who frequently do not see patients with uncomplicated cases. The most important complications reported in the literature are listed in Table 43-2.

One of the commonest of the rare complications is *splenic rupture*, which has led to death in several cases<sup>143,221</sup> and may occur with an incidence of 0.2% or higher. The diagnosis of a ruptured spleen should be entertained whenever a patient with infectious mononucleosis has severe or even moderate pain below the left costal margin, especially if the pain is accompanied by radiation to the left shoulder or evidence of impending peripheral vascular collapse. Other signs include those characteristic of peritoneal irritation, abdominal tenderness, and shifting dullness if massive intra-abdominal bleeding has occurred. Tachycardia is an extremely useful sign since bradycardia is the rule in uncomplicated infectious mononucleosis and rates exceeding 100/minute are rare. Frank rupture may be preceded by one or more episodes of subcapsular hemorrhage or minor capsular tears, which may be difficult to

differentiate from rupture and, since potentially fatal bleeding may occur at any time, some authorities recommend surgical treatment whenever the typical pain pattern is accompanied by increasing tachycardia<sup>143</sup>, rupture with obvious hemorrhage *always* makes surgical therapy mandatory. Delayed surgical intervention is often attributable to the misconception that abdominal pain is a common feature of the uncomplicated disease.<sup>143</sup>

**Cardiac complications** are rare. Electrocardiographic abnormalities, especially non-specific T-wave changes, are the most common and may occur in about 10% of the patients.<sup>70,142</sup> Pericarditis has been reported,<sup>239,253,255</sup> but is very rare; whenever it is found, other causes should also be sought.

**Neurologic manifestations** may occur in 1 to 2% of the patients<sup>143,248</sup> and range from asymptomatic pleocytosis, increased protein in the cerebrospinal fluid, or electroencephalographic abnormalities (which may be found in as many as a third of all subjects) to occasional instances of life-threatening involvement of the nervous system. When serious neurologic complications occur the mortality rate may be as high as 8 to 11%,<sup>128,176</sup> and, in addition, the incidence of serious residual damage may be as high as 12%.<sup>128</sup> Reported neurologic complications are listed in Table 43-2.

The most serious respiratory complication is *acute airway obstruction*, which is usually due to extreme hyperplasia of the tonsils and other pharyngeal lymphatic tissue. Pleural effusion and pulmonary parenchymal changes are exceedingly rare.

Evidence for some degree of *hepatic involvement* is found in the great majority of patients, but is usually mild, and the necrosis and inflammatory exudate that are seen in infectious hepatitis are rarely encountered.<sup>140</sup> Liver failure is exceedingly rare.<sup>224</sup> *Pancreatitis* is an equally rare complication.<sup>86,200,298</sup>

The most common hematologic complications are hemolytic anemia<sup>62,65,113,304</sup> and thrombocytopenia.<sup>38,45,143,232</sup> The incidence of hemolytic anemia may be 3%. Hemolysis

usually is mild; in about 70% of the patients with hemolytic anemia the reaction to Coombs' test is positive and in about the same number the titers of cold agglutinins are increased.<sup>304</sup> Sometimes, however, there is no detectable antibody of any kind. The cold agglutinins are specific for the red cell antigen i,<sup>148,240</sup> (see page 458) but, since a similar incidence of anti-i antibodies (70%) also is found in patients without hemolysis,<sup>148,240</sup> the role of these antibodies in red cell destruction is unclear. The antibody reported in these studies had the characteristics of an IgM molecule, but others have also found IgG anti-i antibodies in the sera of 90% of patients with infectious mononucleosis.<sup>35</sup> The latter incomplete antibody only caused agglutination in the presence of anti-IgG antibodies. Thus, since anti-i antibodies are commonly seen but hemolytic anemia is rare, it is doubtful whether they are the cause

of hemolysis in all patients who have this antibody. In only a few cases has hemolysis been shown to be clearly due to anti-I.<sup>33,35,148,155,279</sup> One case of hemolysis due to Donath-Landsteiner cold hemolysins has been reported.<sup>293a</sup>

In some instances, infectious mononucleosis may have accelerated hemolysis in patients with underlying hereditary spherocytosis<sup>65,113</sup> or thalassemia.<sup>274</sup>

*Thrombocytopenic purpura* is a very rare complication<sup>15,143,232</sup> although mild depression of the platelet count ( $100$  to  $140 \times 10^9/l$ ) may be found in perhaps one half of the patients,<sup>38</sup> usually early in the disease. When thrombocytopenic purpura does occur, most of its subjects seem to be children.<sup>143</sup> As a rule, the purpura develops about a week after the appearance of the first symptoms of infectious mononucleosis and the bleeding manifestations last about 10 days, although some degree of thrombocytopenia persists for a month.

Serious suppression of marrow function is rare, but fatal aplastic anemia was noted in one patient six weeks after what appeared to be typical infectious mononucleosis.<sup>304</sup> The sequence of events in this patient was not unlike that observed in young males who develop fatal marrow aplasia while recovering from infectious hepatitis.<sup>180</sup>

*Granulocytopenia* has been reported in rare instances<sup>82,170a,199,305</sup> but the possibility of other more common causes of granulocytopenia such as drugs could not be excluded in some of the cases.

## Laboratory Findings

### Blood Cells

The characteristic feature of infectious mononucleosis is the polymorphism of the mononuclear cells found in the blood. In addition to normal lymphocytes and monocytes, large mononuclear cells that usually are not present in the blood are observed (Plate XVII). Although not specific,<sup>69</sup> since they

may be found in the blood of patients with viral infections or with a number of other conditions (see below),<sup>303</sup> they form a prominent feature of infectious mononucleosis.

The abnormal cells vary greatly in size and shape. They possess a nucleus that may be oval, kidney-shaped, or slightly lobulated and cytoplasm that most frequently is nongranular and vacuolated or foamy in appearance. The nuclear chromatin forms a coarse network of strands and masses and is not clearly differentiated from the parachromatin. The identity of these cells has been disputed, but most hematologists regard them as highly differentiated, mature lymphocytes.<sup>41,68</sup> They do not show granules when stained for peroxidase and leukocyte alkaline phosphatase, and can thus be distinguished from cells of the granulocytic series and, to some extent, from monocytes.

These "leukocytoid lymphocytes," the form most frequently seen, were classed as Type I by Downey,<sup>68</sup> who described two other types of abnormal lymphocytes in the blood of infectious mononucleosis patients. Compared with Type I cells, Type II cells are less varied but larger, their nuclear chromatin is not so condensed, and their cytoplasm is more homogeneous and not so basophilic or so vacuolated. Type III cells resemble Type I cells but show some leukemic features. Their nuclei show a diffuse sieve-like chromatin and possess one or two nucleoli. Their cytoplasm is vacuolated and may be quite basophilic. Excellent illustrations of these cells were published by Downey and McKinley.<sup>68</sup>

Infectious mononucleosis cells obtained directly from the blood appear to be T cells (page 295)<sup>252a</sup> and may be produced in the thymus-dependent areas of lymph nodes and spleen, since these areas show a great deal of proliferative activity.<sup>78a</sup> In vitro these cells proliferate actively and there is evidence for increased DNA and RNA synthesis, especially early in the disease.<sup>39,78,185</sup> Such cells also have been studied by histochemical methods<sup>100</sup> and with the electron microscope.<sup>218,236</sup>

**HETEROPHIL ANTIBODIES** A serologic diagnostic test for infectious mononucleosis has been available since Paul and associates<sup>221</sup> discovered that the sera of patients with infectious mononucleosis contain agglutinins against sheep red cells. They called the antibody "heterophil," since it reacted with an heterologous antigen that obviously had not elicited its production. Most authorities consider a positive response to the heterophil antibody test to be a *sine qua non* in the diagnosis of infectious mononucleosis.<sup>140,143</sup> It was soon learned that the antibody reacted not only with sheep red cells but also with beef and horse erythrocytes,<sup>4,8</sup> although in different reaction patterns, the mechanism of which is poorly understood<sup>267</sup>; while sheep and horse erythrocytes are readily agglutinated by heterophil antibodies, they are not lysed, whereas bovine red cells are readily lysed, but not agglutinated.<sup>57,175,277,294</sup>

The heterophil antibody is an IgM globulin<sup>41,171,268,291,310</sup> which in some studies<sup>309</sup> was shown to have lambda light chains only. In spite of this relatively homogeneous structure, there seems to be some heterogeneity of antigenic specificity; it has been shown, for instance, that absorption of infectious mononucleosis sera with bovine red cells removes all activity against sheep and horse cells as well, while absorption with sheep cells removes only part of the activity against equine and bovine cells.<sup>245,268,277,294</sup> Thus bovine cells have some antigenic specificities not found on cells from these other sources, and infectious mononucleosis sera contain antibodies against several antigenic specificities.

Our knowledge of the nature of the heterophil antigen is very fragmentary. The antigen has been shown to be thermostable<sup>4</sup> in contrast to the Forssman antigen. Its immunologically reactive sites appear to be carbohydrate in nature, since they are completely destroyed by neuraminidase, but retain their antigenicity in the presence of proteases.<sup>258</sup> When heterophil receptors were extracted from horse erythrocytes with hot 75% ethanol,<sup>93</sup> the material was found to have a carbohydrate content of 40% with a hexose:hexosamine:sialic acid ratio of 1:1:1. The

peptide portion was greatly enriched in acidic and hydroxylamino acids, which accounted for 43% of all amino acids. As in studies with whole red cell preparations (see above), extracts of bovine origin appeared to have some antigenic determinants not shared with sheep and horse red cells.<sup>93</sup> In addition, the bovine antigen has less sialic acid and carbohydrate and more nitrogen than the other preparations, and retains some infectious mononucleosis reactivity after treatment with neuraminidase.<sup>93</sup>

The carbohydrate nature of the antigen probably explains the observation that the antibody response is almost exclusively IgM, as are the antibody responses to other carbohydrate antigens such as certain blood group substances and the salmonella O antigen.<sup>171</sup>

The heterophil antibody test is carried out as follows.<sup>36</sup> The patient's serum is heated for 30 minutes at 56°C to destroy complement. Only 0.1 ml of a 2% suspension of sheep red corpuscles is needed for the test. The cells should not be less than 24 hours old, nor more than a week old. They must be washed three times in physiologic saline solution on the day of the test, mixing them each time with two to three times as much physiologic solution of sodium chloride. The third centrifugation should concentrate the cells to about half their original volume. The supernatant fluid must be clear after the third centrifugation.

Serial dilutions of serum ranging from 1:7 to 1:7168 are mixed with equal volumes of the 2% red cell suspension. A control tube contains saline solution instead of serum. After shaking, the test tubes are allowed to stand at room temperature for two hours. They are then shaken again until the sediment has been suspended. Agglutination of the corpuscles indicates the presence of heterophil antibody in that tube. The highest dilution in which this can be detected with the naked eye, or with the lowpower microscope objective, is taken as the end point.

Antisheep agglutinins are present in titers up to 1:28 in most normal persons, and occasionally even in a titer of 1:56.<sup>57</sup> In various infections a titer of 1:112 and occasionally

Table 43-3. *Differential Test for Infectious Mononucleosis*

+ indicates complete absorption  
 - indicates incomplete absorption  
 ± indicates complete or partial absorption

of 1:224 may be obtained. Persons receiving injections of horse serum and horse immune serum may develop titers as high as any found in infectious mononucleosis. After various kinds of known or unknown antigenic stimulation a titer of 1:448 and higher is occasionally noted.

For these reasons the test for heterophil antibodies has been called *presumptive*.<sup>58</sup> In the presence of clinical and hematologic findings suggestive of infectious mononucleosis, a titer of 1:224 or higher can be interpreted as confirming the diagnosis. In infectious mononucleosis, positive heterophil reactions almost always appear during the first two weeks of the illness.<sup>140</sup> Highest titers are usually found during the second and third weeks. As a rule, positive reactions last four to eight weeks. They have been observed to persist for as short a time as seven to nine days or for as long as 18 weeks.<sup>57</sup> The titer bears no relation to the severity of the disease or to the leukocyte changes. There are wide variations in the agglutinability of erythrocytes from different sheep.

If the titer of the presumptive test is less than 1:224 in the presence of clinical and hematologic findings suggestive of infectious mononucleosis, if the titer is 1:224 or higher in the absence of such findings, or if the patient gives a history of a recent horse serum injection, the results should be checked by a differential test.

The *differential test*<sup>58</sup> is based on the observation that heterophil antibodies in normal serum, in horse serum sensitization, and in

a variety of infections can be absorbed completely by Forssman antigen (guinea pig or horse kidney), but the antibodies present in the serum of patients with infectious mononucleosis are not completely absorbed. On the other hand, absorption with a suspension of beef cells removes the anti-sheep agglutinins completely in infectious mononucleosis, but may leave some antibody in other sera. It is the combination of (1) no or incomplete removal of antibodies with Forssman antigen and (2) complete removal with beef cells (Table 43-3), which is characteristic for infectious mononucleosis. The original differential test offers a very high degree of specificity.<sup>57</sup> A simple capillary screening test has also been devised.<sup>174</sup>

Elevated titers of hemolysin for beef erythrocytes are present in infectious mononucleosis. This forms the basis of another satisfactory test for the disease.<sup>191</sup>

Papain and other plant proteases have been found to remove specifically the receptor for anti-infectious mononucleosis antibodies on sheep erythrocytes without inactivating the receptor for the Forssman and serum sickness antibodies. This is the principle of still another useful diagnostic test<sup>259,300,301</sup> including a simple slide test.<sup>182</sup>

Perhaps one of the easiest and yet most specific tests devised for the diagnosis of infectious mononucleosis is a slide test using formalinized horse red cells as an immunologic indicator.<sup>55,59,147,278</sup> The cells are agglutinated only by the heterophil antibody of infectious mononucleosis and not by any of the

others. This test has many advantages: it seems to be specific, the reagents are available commercially and stable, and the test is easily and rapidly performed in the physician's office. The diagnostic accuracy of the test has been found to be very high (99%),<sup>117</sup> but, since the red cells tend to lose some agglutinability in the process of formalin treatment, the test tends to miss a few low titer sera.<sup>102,175</sup>

Lee and associates have developed a test in which absorptions are performed with the classic combination of guinea pig kidney and boiled ox erythrocytes.<sup>175</sup> The speed of absorption is increased by using very fine suspensions of guinea pig kidney and red cell stromata rather than whole beef red cells. The sensitivity of the test was increased by using horse erythrocytes which are agglutinated to a higher titer than sheep erythrocytes.<sup>175</sup> This test ("Monospot") is probably the most reliable slide test available.<sup>267</sup>

**OTHER ANTIBODIES.** In addition to the heterophil antibody, several other antibodies are found in the sera of patients with infectious mononucleosis. These include cold reactive anti-i antibodies, Donath-Landsteiner cold hemolysins (see page 1363), and an antibody against Rhesus monkey red cells as well as lymphocytotoxins, antibodies directed against specific populations of T and B cells, and smooth muscle antibodies.<sup>76a,212</sup>

Antinuclear antibodies also have been found in the sera of some infectious mononucleosis patients.<sup>77,160</sup> Other patients were found to have a falsely positive reaction to the VDRL test for syphilis, but, according to some authorities, the response to this test may often have been truly positive, since many of the early reports originated during World War II when a true positive VDRL reaction was not rare among young adults.<sup>141</sup>

The sera of some infectious mononucleosis patients also contain *cryoglobulins*.<sup>158,159</sup> The cryoprecipitate consists of IgG and IgM, although IgA may be coprecipitated. Heterophil antibodies, cold agglutinins, rheumatoid factor, antinuclear antibodies, and syphilitic reagins have been reported in connection

with these cryoprecipitates.<sup>158,159</sup> Cold reactive rheumatoid factors have been detected in the sera of over half of the infectious mononucleosis patients.<sup>36,111</sup>

Since so many antibodies have been linked with the development of infectious mononucleosis, it is not surprising that immunoglobulin levels are elevated in this disease.<sup>1,302</sup> While this is especially true for IgM globulins, lesser elevations have also been seen in IgG and IgA globulins. The pattern of changes is similar to that seen in the normal immune response: IgM is elevated first and IgG later.<sup>175</sup> Antibodies with recognized antigenic specificities such as the heterophil antibody only make up a small proportion of the total gamma globulins of the serum<sup>179,302</sup> and the antigenic specificity of the major portion of the increased gamma globulins remains unknown.

### Other Laboratory Findings

Many patients with infectious mononucleosis show mild to moderate abnormal responses to *liver function tests*.<sup>61,143</sup> The reported incidence has varied from about 40 to 100%, depending on the severity of the disease, the time of testing, and the diligence with which the changes were sought. Reported enzyme changes include elevations of isocitric dehydrogenase, alkaline phosphatase, lactic dehydrogenase, glutamic pyruvate transaminase, phosphohexose isomerase, and aldolase, in roughly that order of frequency. Positive reactions to flocculation tests are common and response to the BSP retention test may also be abnormal. Perhaps a third of the patients have mild to moderate elevations of serum bilirubin, but levels above 8 mg% are exceedingly rare.<sup>143</sup> Dissociation between serum alkaline phosphatase and serum bilirubin values has been reported,<sup>6,254</sup> but the practical value of this observation is doubtful. Because manifestations of impaired liver function tend to rise and fall concomitantly and are most pronounced by the middle or end of the second week of the infection (Fig. 43-4), it is unnecessary to order batteries of tests.

Fig 43-4 Major laboratory findings in adults with infectious mononucleosis (From Finch,<sup>91</sup> courtesy of the author and Blackwell Scientific Publications)

The urine usually is normal. Occasionally, proteinuria or hematuria is present. Mild pyuria also has been noted. In many cases the described abnormalities are not related to infectious mononucleosis *per se*. Renal function is unimpaired. When the patient is jaundiced, bile and increased concentrations of urobilinogen may be found.

The cerebrospinal fluid pressure may be elevated, and there may be pleocytosis and increased levels of protein. The sugar content is normal. In a few of the patients, heterophil antibodies have been demonstrated in the CSF.<sup>90</sup>

### Differential Diagnosis

The diagnosis of infectious mononucleosis usually presents no problem. In most instances a young adult complains of malaise, fatigue, anorexia, and a sore throat, and is found to have fever, adenopathy, pharyngitis, and splenomegaly. Examination of the blood and, above all, a heterophil antibody test and/or a rising EBV titer confirm the diagnosis. Complications are very rare and signs of significant respiratory, cardiovascular, intestinal, urinary, or joint disease make consideration of other diagnoses mandatory. Other manifestations, such as a nasal dis-

charge or congestion, painful or extremely tender nodes, watery diarrhea, and signs suggestive of acute appendicitis, are so rare in infectious mononucleosis as to militate against this diagnosis.<sup>140</sup> Sometimes the characteristic clinical findings of infectious mononucleosis are not apparent until the end of the second week of illness, and heterophil antibodies may not be detectable for a week or so.

The *pharyngitis* of infectious mononucleosis must be differentiated from acute streptococcal pharyngitis, diphtheria, and acute viral pharyngitis of other types. The *fever and general malaise* may suggest one of the salmonella infections, listeriosis, brucellosis, subacute bacterial endocarditis, the lymphadenopathic form of toxoplasmosis, or malaria. Drug fever and serum sickness-like reactions may also suggest infectious mononucleosis, since they are often characterized by fever, jaundice, lymph node enlargement, and atypical lymphocytes. Clinical features should suffice to differentiate the *lymph node enlargement* of infectious mononucleosis from that occurring regularly in Hodgkin's disease and in lymphosarcoma, and that which may be seen with neoplastic metastases and inflammatory disease. Generalized lymph node enlargement, including the

nodes in the postauricular and occipital areas, is also characteristic of rubella, however. In addition, a palatine exanthem may be present in as many as a third of all patients with rubella<sup>113</sup> and atypical lymphocytes have been described.

The hematologist is most frequently called upon to differentiate infectious mononucleosis from other hematologic diseases, especially acute leukemia, but the latter diagnosis should never be made in the absence of other hematologic manifestations such as anemia, thrombocytopenia, and typical blast cells. Although many leukocytes of patients with infectious mononucleosis appear abnormal, very few contain nucleoli, and thrombocytopenia and anemia are very rare in these patients. It should also be noted that the appearance of the peripheral blood is constantly fluctuating in infectious mononucleosis, whereas this does not happen in leukemia. Bone marrow examination is rarely necessary to differentiate infectious mononucleosis from acute leukemia.

Patients who have suffered from infectious mononucleosis do not have a higher incidence of leukemia, lymphoma, or other malignant conditions subsequently,<sup>193a</sup> but a few cases of concurrent infectious mononucleosis and leukemia have been reported.<sup>61,94,95,204</sup> Indeed, intercurrent infectious mononucleosis has been considered to have a beneficial effect on the survival of patients with acute leukemia.<sup>206</sup> In addition, the sera of all acute leukemia patients with long survivals had higher immune anti-EBV titers than did the sera of control groups. The basis of the beneficial effect of infectious mononucleosis on acute leukemia is unknown and may be nonspecific; the two diseases appear to be etiologically unrelated.<sup>94,95</sup>

*Lymphocytosis*, absolute or relative, may be encountered in a number of diseases other than infectious mononucleosis, as discussed in Chapter 41. These include agranulocytosis, Vincent's angina, tuberculosis, tularemia, pertussis, dengue, mumps, chickenpox, German measles, typhoid fever, infectious hepatitis, serum sickness, and various other allergic states. In some of these conditions, abnormal lymphocytes resembling those of

infectious mononucleosis have been observed, as mentioned earlier. Differentiation from infectious hepatitis sometimes is difficult but reaction to the differential test for heterophil antibodies is negative in the latter.

Marked leukocytosis, due chiefly to the presence of small lymphocytes of normal appearance, and associated neither with splenomegaly, lymphadenopathy, nor a positive heterophil agglutination reaction, suggests acute infectious lymphocytosis (Chapter 41, page 1289).

Atypical lymphocytes have also been described in the post-transfusion syndrome, an infectious mononucleosis-like illness occurring particularly commonly after cardiopulmonary bypass.<sup>157,168,251,256,261</sup> The illness usually occurs one to three months after open heart surgery or after blood transfusions and is characterized by moderate fever, and, in about half the patients, splenomegaly or hepatomegaly. Lethargy and adenopathy are unusual and pharyngitis is absent, thus differentiating this syndrome from infectious mononucleosis on clinical grounds alone. A transient rubelliform rash is occasionally present.<sup>256</sup> The disease is caused by the cytomegalovirus (CMV) and the virologic diagnosis can be confirmed by demonstrating a serial rise of complement-fixing antibodies to CMV. The virus may also be cultured from the patient's blood and tissues. Reactions to tests for heterophil antibodies are characteristically negative and serial increases in anti-EBV titers have not been noted in CMV infections.<sup>261</sup>

Lymphocytosis with atypical cells is the most characteristic laboratory feature of the post-transfusion syndrome, and the peripheral smear may be indistinguishable from that of infectious mononucleosis. The white count usually does not exceed 15.0, but occasionally leukemoid reactions with counts of 35.0 to 75.0  $\times 10^9$  cells/l may be obtained.<sup>157</sup> The bone marrow is said to be normal in appearance. A normochromic normocytic anemia with varying degrees of reticulocytosis is not uncommon and in some instances, at least, appears to be associated with a positive reaction to Coombs' test or with cold agglutinins.<sup>157</sup> Other immunologic "aberrations"

include rheumatoid factors, antinuclear antibodies, and cryoglobulins.<sup>157,168</sup> In most patients with CMV the infection is mild and resolves within a few weeks; in a few the manifestations may last for several months or longer.

### Treatment

There is no specific therapy for infectious mononucleosis. Antibiotics are of no value<sup>249</sup> unless the patient has developed a superimposed streptococcal pharyngitis. Convalescent sera, obtained from patients one or two weeks after they had become free from fever, and given intravenously in total doses of 50 to 300 ml, have been found useful in bringing about symptomatic relief and fall of temperature, and in preventing complications.<sup>172</sup> There is no convincing evidence that chloroquine is beneficial.<sup>309</sup> Adrenocorticosteroids may have dramatic effects on the disease with prompt lysis of fever and visible reduction of lymphatic hyperplasia, usually within 24 hours. Steroids are indicated<sup>2,13,70,143</sup> in patients with hemolytic anemia, thrombocytopenia, and with neurologic complications. They are also recommended for unusually distressing sore throats and when there is incipient airway obstruction. The prolonged use of steroids should be avoided.

Isolation of patients does not seem warranted, since cross infection has not been noted under ordinary circumstances.<sup>15,140</sup> Bed rest need not be enforced and return to normal activities should be governed by the improvement in clinical manifestations of the disease. It has been recommended<sup>143</sup> that patients not travel by automobile for a minimum of three weeks after the onset of symptoms, because of the possibility of a fatal splenic rupture resulting from even rather minor abdominal trauma.

### Prognosis

Infectious mononucleosis is rarely fatal and the prognosis for a complete recovery within two months is virtually 100%<sup>143</sup>; recurrences

of infectious mononucleosis are either extremely rare or nonexistent.

Penman,<sup>224</sup> in reviewing the world literature on infectious mononucleosis, catalogued 87 fatalities attributed to the disease or its complications. However, only 20 of these reports contained adequate evidence for an unequivocal diagnosis of infectious mononucleosis. In the 20 cases, 9 fatalities were due to neurologic complications—four due to respiratory failure from peripheral neuropathy of the Guillain-Barré type and five due to central respiratory paralysis; three were due to splenic rupture and three to secondary infection; other fatal complications included hepatic failure (2 cases) and myocarditis (1 case); in two cases the cause of death was unrelated to infectious mononucleosis.

The actual incidence of fatal complications is difficult to estimate but appears to be less than one per 3,000 cases.<sup>224</sup>

### Pathology

Infectious mononucleosis is a systemic illness whose main pathologic feature is a marked proliferative response within the reticuloendothelial system, especially the lymph nodes and the spleen. Nevertheless, perivascular infiltration by normal and atypical lymphocytes may also occur in many other organs of the body.

The lymph node architecture<sup>48,101,235</sup> may be distorted but is otherwise intact,<sup>101</sup> and this helps to distinguish infectious mononucleosis from malignant lymphomas. The germinal centers are identifiable, but follicular prominence is diminished. This probably is due to the irregular and vaguely defined borders that result from the lymphocytic and reticuloendothelial hyperplasia of perifollicular structures, and especially the medullary cords.<sup>48</sup> In addition, there is focal proliferation of macrophages, and, most characteristically, the presence of "typical" infectious mononucleosis cells throughout the pulp, on the edges of germinal centers, and in the sinuses.<sup>101</sup> Nasopharyngeal lymphoid hyperplasia was consistently found in the autopsy subjects.

The spleen shows striking infiltration of its

fibromuscular structures by mononuclear cells<sup>48, 143</sup>; both the capsule and trabeculae are thin and invaded by proliferating lymphocytes, and thus probably explains the unusual liability to splenic rupture in this disease.

Some enlargement of the liver is frequently seen in patients who come to autopsy.<sup>45</sup> Collections of mononuclear cells are seen throughout the portal areas, throughout the lobules, and within sinuses.<sup>141</sup> Most of these cells are small lymphocytes, but cells corresponding to atypical lymphocytes are also found. Small numbers of eosinophils may be present in the portal areas. Hepatocellular damage is minimal or absent<sup>141, 258</sup> and this feature sharply differentiates infectious mononucleosis from infectious hepatitis. Infectious mononucleosis never leads to cirrhosis of the liver.<sup>143</sup>

The meninges<sup>18</sup> may be congested and edematous and occasional small perivascular hemorrhages are noted. Some patients coming to autopsy have shown evidence of a mild to moderate meningoencephalitis and in some distinct perivascular cuffing is evident within the brain. Changes in the spinal cord appear to be minor, but cellular infiltration of anterior roots has been noted.<sup>18</sup>

Small focal infiltrations of the lungs,<sup>48, 311</sup> kidneys,<sup>48, 311</sup> and myocardium<sup>48</sup> explain some of the minor clinical manifestations of this disorder.

## Immune Deficiency Diseases

### Definition and Terminology

Infantile Sex-Linked Agammaglobulinemia  
Selective Immunoglobulin Deficiency (IgA)  
Transient Hypogammaglobulinemia of Infancy  
Immunodeficiency with Hyper IgM  
Thymic Hypoplasia  
Immunodeficiency with Ataxia Telangiectasia  
Immunodeficiency with Thrombocytopenia and Eczema  
Severe Combined Immunodeficiency  
Variable Immunodeficiency  
Other Congenital Disorders of Host Defense against Infections  
Acquired Immune Deficiency Syndromes

### Definition and Terminology

Since Bruton's original discovery of agammaglobulinemia in 1952,<sup>5</sup> several thousand patients suffering from a variety of immune deficiency states have been studied in clinics and laboratories throughout the world. It soon became clear that immunologic deficiency can take many forms with a bewildering array of clinical, pathologic, and immunologic findings. Unfortunately, the use of eponyms, inaccurate terminology, and hypothetical pathogenetic mechanisms led to further confusion.

Two broad categories of immune deficiency states—primary and secondary—are now recognized. Primary immune deficiency diseases are genetically determined abnor-

malities of immunologic development that result in defective antibody production or cellular immune responses. Secondary immune deficiencies are due to acquired diseases that interfere with the function of the mature immune system.

While the classification of secondary immune deficiencies presents little difficulty, classification of the primary or inherited defects has generally been unsatisfactory. In an attempt to clarify the categorization the World Health Organization convened a group of investigators who proposed a classification of primary immune deficiencies based on the apparent cellular defect involving stem cells, B-cells, or T-cells (for a discussion of these cells, see Chapter 7) or a combination of these<sup>6</sup> (Table 44-1). Thus, for example, infantile sex-linked agammaglobulinemia is thought to be caused by an almost complete lack of B-cell function, while thymic hypoplasia is the prototype of T-cell defects. Each defect is associated with fairly predictable clinical, pathologic, and immunologic findings, but these may vary somewhat depending on whether the defect is partial (eg, selective immunoglobulin deficiency) or complete (eg, infantile sex-linked agammaglobulinemia) and whether there are other associated defects (eg, hypocalcemia in thymic hypoplasia, thrombocytopenia, and eczema in the Wiskott-Aldrich syndrome). Because of these individual variations it is necessary to consider the major immune deficiency syndromes separately. The terminology proposed by the

Table 44-1. Congenital Immunologic Deficiencies

<sup>a</sup>See also Figure 7-5 (Page 294)

World Health Organization will be used throughout this chapter, but eponyms will be given where this facilitates understanding or access to the older literature.

A comprehensive classification of acquired immune deficiency syndromes is presented in Table 44-2. Only those of special hematologic interest are dealt with in detail here, but appropriate references are listed for all. The immunosuppressive agents are discussed in the chapter on chemotherapy of leukemia and lymphomas (Chapter 55).

### Infantile Sex-Linked Agammaglobulinemia (Bruton's Agammaglobulinemia)<sup>4,5,10,12,22</sup>

#### Clinical Manifestations

Infantile sex-linked agammaglobulinemia was the first immunologic deficiency disease

to be described in detail.<sup>5</sup> It is characterized by an almost complete lack of B-cell function; once the transplacentally acquired maternal gamma globulin is lost, serum gamma globulins of all classes reach very low levels and in many individuals concentrations of 15 mg/dl or less are found. All of these patients produce antibodies poorly and many cannot produce any detectable levels of specific antibodies, even after repeated and intensive antigenic stimulation. As a result, boys with sex-linked agammaglobulinemia suffer from recurring pyogenic infections that usually involve the lungs, sinuses, inner ears, meninges, or intestinal tract. Highly encapsulated organisms are the most common offenders and among these pneumococci are preeminent, followed by *Hemophilus influenzae*, streptococci, meningococci, staphylococci, and *Pseudomonas aeruginosa*.<sup>10,12</sup> In contrast to their extreme susceptibility to pyogenic infections, patients with sex-linked agammaglobulinemia experience little difficulty in

combating recurring viral or fungal infections and react appropriately to smallpox vaccination.<sup>7,18</sup> The common viral diseases of childhood such as measles, German measles, mumps, and chickenpox are usually weathered in normal fashion. One exception to this general pattern of behavior appears to be an increased susceptibility of these patients to the infectious hepatitis virus; infection with this virus may lead to a progressively active or fulminating form of hepatitis resulting in death.<sup>20</sup> This susceptibility must be borne in mind when transfusion therapy is planned for patients with agammaglobulinemia. A number of patients have died from infection with *Pneumocystis carinii*, but successful ther-

apy with pentamidine isethionate has been reported.<sup>23</sup>

In spite of their inability to produce antibodies against most ordinary antigens, patients with agammaglobulinemia are not free from illnesses usually considered to be immunologic in nature. Indeed, diseases such as chronic synovitis, rheumatoid arthritis, dermatomyositis, scleroderma, and diffuse vasculitis occur with inordinate frequency, perhaps approximating an incidence some 20 to 30 times greater than that in the general population.<sup>11,13,19</sup> The rheumatoid arthritis, however, is usually, though not always, rheumatoid-factor negative.<sup>27</sup> In addition, hemolytic anemia, sometimes Coombs' positive,

and episodes of leukopenia and thrombocytopenia have been described.<sup>13</sup> A number of patients have developed amyloidosis. Steatorrhea is not uncommon in hypogammaglobulinemic patients. Its incidence is particularly high in those with the idiopathic acquired forms (see below), but several cases also have been reported in patients with the congenital varieties.<sup>3,4,16</sup> Patients with agammaglobulinemia also develop leukemia and lymphoid malignant diseases with exceptional frequency<sup>13,21</sup>; the incidence has been estimated at about 5%.<sup>9</sup> The high incidence of leukemia in this condition is of interest in view of the demonstrated importance of humoral mechanisms in the defense against certain forms of mouse leukemia.<sup>14</sup>

On physical examination, patients with sex-linked agammaglobulinemia show evidence of chronic sepsis and its complications. In untreated patients, severe growth retardation may be noted. Lymphoid tissues such as tonsils and nodes accessible to palpation are grossly normal.

### Immunologic Findings

1. The lymphocyte count is normal, but most of the lymphocytes are T-cells; B lymphocytes bearing all classes of surface immunoglobulins are lacking in the blood and bone marrow of most patients,<sup>1a,2,8,15</sup> while some have low concentrations of IgM- and IgA-bearing cells but no IgG-bearing B cells.<sup>8</sup> Plasma cells are greatly reduced or absent from the marrow,<sup>1</sup> the lymph nodes, and the lamina propria of the glands and bowels.

2. All classes of immunoglobulins, including the secretory immunoglobulins, are deficient. Isohemagglutinin titers and heterophil titers are very low or zero and antibody responses, even after repeated antigenic stimulation, are extremely deficient or completely absent. Reaction to the Schick test remains positive even after repeated immunizations with diphtheria toxoid, although it may become negative if patients are treated with exogenous gamma globulin containing diphtheria antitoxin.

3. Abnormalities of complement have

been described.<sup>24</sup> The concentration of the C1q subunit of C1 is often one half to two thirds of the normal mean, but the C1s activity is normal (see Chapter 7 for a discussion of complement). C1 hemolytic activity is variably depressed.<sup>24</sup>

4. Cellular immune responses are intact; delayed hypersensitivity responses to such antigens as *Candida*, diphtheria toxoid, mumps, and tuberculin are normal and deliberate sensitization to contact allergens such as 2,4-dinitrochlorobenzene (DNCB) usually is successful. In vitro lymphocyte proliferation in response to phytohemagglutinin (PHA), allogeneic cells, and appropriate antigens to which the patient has been previously sensitized is normal. Allogeneic skin grafts are rejected normally, although perhaps a few days later than in completely immunocompetent individuals.<sup>13</sup>

### Pathology

The basic structure of the thymus is intact although a certain amount of stress involution often is seen. The paracortical regions of nodes are usually normal, but the follicles are poorly developed and lack germinal centers even in specifically stimulated nodes. Plasma cells are lacking. The tonsils have poorly developed crypts and lack germinal centers and plasma cells; small accumulations of lymphocytes may be found in the pharyngeal areas. The Peyer's patches are poorly developed and lack follicles, and plasma cells are absent from the lamina propria of the intestinal tract and the secretory glands.

### Treatment

The mainstay of therapy is the monthly injection of alcohol- or ether-fractionated immunoglobulin at a minimum dose of 100 to 200 mg/kg of body weight/month. Injections of 100 mg/kg will result in an increase of serum IgG of 100 to 200 mg/dl. It is probably wise to aim for minimum residual serum levels of at least 200 mg/dl just prior to the next injection. This level is usually not difficult to achieve because of the marked decrease in the fractional catabolic rate of

immunoglobulins in hypogammaglobulinemic patients if there is no gastrointestinal protein loss.<sup>28</sup> With regular injections of gamma globulin, patients with sex-linked hypogammaglobulinemia have reached adult life; they rarely suffer from specific viral exanthems and a statistically significant beneficial effect on the incidence of bacterial infections was shown in a controlled trial of patients with hypogammaglobulinemia.<sup>17</sup>

Most available gamma globulin preparations consist largely of IgG (95%) with about 5% IgA. The effect of treatment is thus mainly confined to antibodies within the circulation and the interstitial fluids. It is therefore unlikely that gamma globulin injections serve the functions of secretory IgA; indeed it has been shown that, while patients can be relieved of their systemic infections such as pneumonia, meningitis, and septicemia, they have continued difficulty in combating infections of the mucous surfaces, particularly those of the respiratory tract, unless they are capable of producing at least small amounts of secretory IgA.<sup>25</sup>

Injections of gamma globulin may be associated with a variety of reactions including local pain, fever, rashes, dyspnea, hypotension, collapse, and even death, but these are rare in sex-linked agammaglobulinemia. The causes of these reactions are unclear; some have been thought to be complement mediated, whereas others have been attributed to antibodies against IgG or gamma globulin allotypes.<sup>6</sup> Some reactions are clearly associated with aggregation of gamma globulins within injected preparations; various tests for aggregation are available<sup>6</sup> and should be used whenever such reactions are suspected. Preparations intended for intramuscular use must never be given intravenously because of the frequency of severe reactions.

Hyperimmune immunoglobulin from normal donors who have recently recovered from specific infections may be of value for agammaglobulinemic patients exposed to these infections.

The intravenous infusion of plasma from selected donors permits replacement of a wider range of immunoglobulins.<sup>6a,26</sup> In addition, larger quantities of gamma globulins

can be given and this permits treatments to be more widely spaced. Such therapy is of special benefit in patients with severe hypogammaglobulinemia, but extreme care must be taken in the selection of donors because of the poor prognosis of agammaglobulinemic patients with infectious hepatitis.<sup>20</sup> Plasma should not be given to individuals with anti-IgA antibodies unless the plasma is derived from IgA-deficient donors.

Since recurrent sinobronchial infections are little affected by gamma globulin injections, prophylaxis with continuing postural drainage, deep-breathing exercises, and other means of maintaining good pulmonary hygiene are mandatory features of long-term management. Treatment to combat individual infections should be given early, employing full doses of specific antibiotics, preferably of limited range. In addition, short courses of antibiotics to eliminate offending organisms are sometimes indicated even in the absence of clinical signs of infections, but prolonged antibiotic prophylaxis is unwise in most instances.

## Selective Immunoglobulin Deficiency (Especially IgA)<sup>16,35,37,38,40,42,43,45,47,50</sup>

### Clinical Manifestations

A marked deficiency of IgA in serum and secretions is not uncommonly found<sup>37,39,42,43,47</sup>; its incidence may be in excess of 1:700 in unselected clinically healthy individuals or blood donors.<sup>37,43</sup> In addition, however, a large number of individuals have been described who have had significant disease in association with selective IgA deficiency.<sup>16,33,38,40,50</sup> In such patients the clinical manifestations are of three major types.<sup>16,33,41</sup>

*Sinopulmonary disease* is seen in about one to two thirds of these patients<sup>33,46</sup> and usually takes the form of recurrent upper respiratory tract infection. In patients with selective IgA deficiency, respiratory disease usually is mild or only moderately severe<sup>16,35</sup> in contrast to

the severe manifestations seen in patients lacking all classes of immunoglobulins. It is of interest, however, that the incidence of respiratory tract infections is lower in patients who lack both IgE and IgA (but not IgG and IgM) than in those lacking IgA only.<sup>46</sup> The reasons for this difference are not understood. Severe asthma also occurs with increased frequency in patients with selective IgA deficiency.<sup>35</sup> This is of interest in view of the fact that IgA is the major blocking antibody found in secretions following hyposensitization.<sup>49</sup> An apparent association between pulmonary hemosiderosis and selective IgA deficiency also has been recognized.<sup>13</sup>

A *sprue-like syndrome* occurs predominantly in adults with IgA deficiency. Its clinical manifestations are surprisingly similar to those of common, nontropical sprue, including improvement on a gluten-free diet,<sup>16</sup> although IgA levels do not improve concomitantly. Some authors have been impressed by the lack of an associated susceptibility to respiratory infections.<sup>16</sup> Histologically there is villous atrophy of the duodenal and jejunal epithelium and scarcity of IgA-producing cells. In contrast, the number of IgM-producing cells may be markedly increased.<sup>16,43</sup> Two patients were found to have anti-ileum basement membrane antibodies,<sup>35</sup> but the role of this antibody in the pathogenesis of the disease is unknown.

Gastric adenocarcinoma has been present in several patients with various types of IgA deficiency, including one individual with a selective IgA deficiency.<sup>9</sup>

A large number of "autoimmune" diseases occur in association with IgA deficiency.<sup>35</sup> Rheumatoid arthritis and systemic lupus erythematosus appear to be the most common, but dermatomyositis, pernicious anemia, thyroiditis, Addison's disease, chronic active hepatitis, and Coombs'-positive hemolytic anemia have been described. The relationship of the IgA deficiency to the development of autoimmune phenomena is not clear but it has been suggested that secretory immunoglobulins may normally serve to block viral, bacterial, and other antigens, which, if

allowed to enter, may lead to the production of autoimmune phenomena.<sup>41</sup>

### Inheritance

Although the majority of cases occur sporadically, in some families genetic patterns which suggest autosomal recessive or autosomal dominant inheritance have been established.<sup>35,45</sup> In addition, IgA deficiency appears to be particularly common in relatives of patients with various other types of congenital agammaglobulinemia.<sup>16</sup> Selective IgA deficiency occurs frequently in association with abnormalities of chromosome 18.<sup>35</sup> In addition, some children have IgA deficiency together with a variable mixture of congenital malformations, mental retardation, and epilepsy.<sup>35,50</sup>

Occasional well-documented cases of acquired selective IgA deficiency have been reported.<sup>35</sup>

### Immunologic Findings

1. The lymphocyte count is within the normal range. Normal numbers of plasma cells are found in the bone marrow and lymphoid organs, but among these cells the number producing IgA is greatly reduced or absent, particularly in the lamina propria. Surprisingly, however, the number of circulating IgA-bearing lymphocytes is either normal or increased,<sup>51</sup> suggesting a defect in differentiation from lymphocytes to plasma cells. In the gut there is often a compensatory increase in IgM-producing cells.<sup>48</sup>

2. Both exocrine and circulatory IgA's are absent, but other immunoglobulin levels generally are normal. IgM levels in secretions may be increased in some patients.<sup>48</sup> Antibody responses are normal with the exception of IgA antibodies.<sup>44</sup>

3. Cellular immune responses are normal.

4. A number of abnormal antibodies and immunoglobulins have been described, including: (a) A high incidence of antimilk and antiovine antibodies.<sup>35,45</sup> The latter are IgG antibodies directed against normal serum from cows, goats, and sheep that also show cross reactivity with milk<sup>35</sup>; these antibodies

appear to be directed against the IgM of the animal concerned. (b) Antibodies against human IgA are found in about 40% of patients and a similar number have anti-IgG antibodies.<sup>35</sup> There appears to be no correlation with previous gamma globulin therapy or plasma administrations. (c) Low molecular-weight IgM (7S IgM) is noted in some patients. (d) A variety of autoantibodies have been described including antinuclear antibodies, antithyroid antibodies, antithyroglobulin antibodies, anti-smooth muscle antibodies, and anti-bile canaliculi antibodies.<sup>35</sup> In many patients these antibodies are not associated with overt autoimmune disease. The antibodies reacting with ileal basement membrane have been described previously (page 1382). Nodular lymphoid hyperplasia within the lamina propria has been reported in patients with other forms of agammaglobulinemic lymphoid enteropathy, but is not found in patients with isolated IgA deficient sprue.<sup>16</sup>

### Treatment

The general care of patients with sinopulmonary complications is similar to that described for agammaglobulinemic patients (page 1381), but injections of gamma globulin are seldom of any use. When patients with selective IgA deficiency develop anti-IgA antibodies,<sup>35</sup> severe hypersensitive reactions and even lethal anaphylaxis may follow the transfusion of normal plasma or blood. Such individuals must be transfused only with blood derived from IgA-deficient donors.

Patients with selective IgE deficiency also have been reported.<sup>46</sup> Most are free from recurrent infections.

## Transient Hypogammaglobulinemia of Infancy<sup>23,61,62</sup>

### Clinical Manifestations

At birth the full-term human infant is amply endowed with passively acquired maternal gamma globulin (1000 mg/dl) which

consists mostly of IgG (see Chapter 7). Because the half-life of these antibodies is approximately 21 days the newborn's gamma globulin levels drop rapidly. Ordinarily, however, the normal newborn begins to synthesize IgM antibodies at birth and attains 75% of adult levels by one year of age. Appreciable IgG synthesis starts a little later, probably during the second month of life and levels of about 800 mg/dl are reached by the end of the first year. As a result of declining maternal gamma globulin levels and increasing gamma globulin synthesis by the infant, the nadir of the gamma globulin levels is ordinarily reached between the third and fifth month of life. Rarely there is an abnormally prolonged delay in the onset of gamma globulin synthesis by the infant and levels may temporarily drop to those ordinarily present in infants with sex-linked agammaglobulinemia. This unphysiologic event has been designated "transient hypogammaglobulinemia of infancy." Its incidence is the same in males and females. Recovery usually occurs when the infant is between 9 and 15 months of age, but some individuals may have persistently low IgG levels later in life as well.<sup>63</sup> Before normal immunoglobulin synthesis begins, infants with transient hypogammaglobulinemia may display an undue susceptibility to infections of the skin, upper respiratory tract, lungs, and meninges, usually with highly encapsulated organisms of the type encountered in persons with congenital sex-linked agammaglobulinemia. At this point the two conditions may be clinically indistinguishable.

### Laboratory Findings

1. The number of circulating *lymphocytes* is normal and plasma cells, ordinarily sparse this early in life, are absent.
2. IgG is primarily depressed, but other *immunoglobulin* values may also be low. Antibody responses to most antigens are low or absent.
3. *Cellular immunity* is normal.
4. Germinal centers are lacking within the peripheral lymphoid tissues.

## Therapy

When therapy is necessary, it is similar to that described for congenital sex-linked agammaglobulinemia.

## Immunodeficiency with Hyper IgM<sup>64</sup>

Immunodeficiency with hyper IgM is a partial immunoglobulin defect characterized by deficiency of IgG and IgA, but increased levels of IgM. The disorder may be congenital or acquired and may be found in either sex but occurs most frequently as an apparent sex-linked gene defect.

Patients affected with this disease suffer from repeated bouts of infection with pyogenic organisms, even though antibody activity against some, but not all, antigens has been demonstrated within the IgM fraction. In addition, these patients frequently suffer from hemolytic anemia, recurrent or persistent neutropenia, and thrombocytopenia. Apparently they have a normal total number of B lymphocytes.

Regular prophylactic administration of IgG will prevent most of the infections.

## Thymic Hypoplasia (Pharyngeal Pouch Syndrome, Di George Syndrome)<sup>68,69,74,75,76,78</sup>

### Clinical Manifestations

The prototype of T-cell defects is the syndrome of thymic hypoplasia, which was initially recognized as such by Di George<sup>68</sup> although the first case was probably recorded as early as 1829.<sup>71</sup> This syndrome is due to faulty development of structures derived from the third and fourth pharyngeal pouches, including the thymus, the parathyroid glands, and, sometimes, the blood vessels of the neck and the esophagus. Since the lack of parathyroids leads to tetany in the neonatal period, hypocalcemia is the first clue

to the diagnosis of this disorder. Because the lack of a thymic anlage leads to deficient T-cell function (Chapter 7), these patients soon develop infections that are normally controlled by cellular immune phenomena. Thus they are particularly susceptible to infection with fungi, especially *Candida*; viruses such as vaccinia, rubeola, and cytomegalovirus; *M. tuberculosis*; atypical acid-fast bacilli; BCG; *Listeria*; and *Pneumocystis carinii*. In the absence of attempts at definitive therapy (see below), death due to disseminated sepsis usually occurs during the first year of life. Failure of growth and "runting" with virtual disappearance of all subcutaneous fat is a characteristic finding during the later stages of life.

### Laboratory Findings

1. *Lymphocyte counts* are variable, but surprisingly the number of these cells is usually within the normal range. The lymphocytes grow poorly in culture, however, and attempts to stimulate their proliferation with specific antigens, PHA, or antilymphocyte sera generally are unsuccessful.<sup>69</sup> Normal or increased numbers of plasma cells are found in the bone marrow and lymph nodes, and in the lamina propria lining hollow organs.

2. *Immunoglobulins* are found in normal concentrations, except that sometimes IgE levels may be elevated.<sup>69</sup> Antibody responses were studied in one patient and were normal for some antigens such as A and B blood group substances and *E. coli*, but were poor or completely lacking for other antigens such as diphtheria-pertussis and tetanus (DPT), poliomyelitis and inactivated measles vaccines, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Candida*.<sup>69</sup> Presumably the latter are thymus-dependent antigens (page 316).

3. *Cellular immunity* is almost totally lacking; there are no delayed hypersensitivity responses to antigens of known exposure, including *Candida*, and it is impossible to induce sensitization with DNCB. Allogeneic skin grafts are not rejected. The behavior of lymphocytes in vitro was discussed above.

## Pathology

Serial sections of the anterior neck and mediastinal tissues fail to reveal any thymic or parathyroid tissue. Lymph node biopsy specimens initially show depletion of thymus-dependent areas and preservation of thymus-independent areas such as follicles, germinal centers, and medullary cords. Plasma cells are abundant. At postmortem examination, marked general lymphoid depletion is seen, probably because of severe terminal sepsis.

## Treatment

Effective therapy has been accomplished by the transplantation of fetal thymic tissue.<sup>66,67</sup> This presumably provides a micro-environment that allows lymphoid precursors to differentiate into thymus-derived small lymphocytes. Unfortunately, the acquisition of immune competence will almost invariably lead to rejection of the thymic transplant and repeated thymic transplants may become necessary.<sup>41</sup> One patient, however, was well 5½ years after receiving a thymic transplant.<sup>48</sup> Apparently spontaneous recovery has also been reported.<sup>44</sup>

Since patients with thymic hypoplasia are incapable of rejecting histoincompatible cells, transfusions with whole blood containing viable immunocompetent lymphocytes may initiate rapidly fatal graft-versus-host disease. It is therefore imperative to irradiate donor blood with at least 3000 rads prior to transfusion.<sup>42</sup>

## Other Forms of Thymic Hypoplasia

A number of patients have been described who likewise manifest cell-mediated immune deficiency syndromes in the face of normal immunoglobulin levels, but have normal parathyroid function.<sup>65,70,77</sup> At postmortem examination the thymus has been absent or aplastic while plasma cells have been found in abundance. With the exception of endocrine abnormalities the clinical course of these patients has been similar to that of

patients with the pharyngeal pouch syndrome. One patient has been described, however, in whom thymic hypoplasia and defective cellular immunity were accompanied by hypothyroidism and normal parathyroid function.<sup>73</sup> It was thought that this patient suffered from a developmental defect involving the second and third pharyngeal pouches.

## Immunodeficiency with Ataxia Telangiectasia<sup>83,84,86,87,90,92</sup>

### Clinical Manifestations

Ataxia telangiectasia is a familial disease the cardinal features of which consist of (1) progressive cerebellar ataxia, (2) progressive oculocutaneous telangiectasis, (3) severe sinopulmonary infections, and (4) an extremely high incidence of lymphoreticular malignant disease. The immunologic defect is thought to involve both T-cells and B-cells but not stem cells.

The *neurologic* manifestations<sup>83,84</sup> are usually the first to appear, frequently when the child begins to walk. In addition to progressive cerebellar signs, other features include choreo-athetoid and tic-like movements, occasional myoclonic jerks, and apraxia of eye movements simulating ophthalmoplegia. Although mental deficiency is not found during the early stages of the disease, the intelligence quotient is said to drop below the normal range as the illness progresses. In the cerebellum there is severe degeneration of the Purkinje cells. Less pronounced degenerative changes are found elsewhere in the brain. Their cause is not known; it is not obviously vascular.

*Oculocutaneous telangiectases*<sup>91</sup> usually appear when the patient is five or six years of age; the bulbar conjunctiva is most characteristically involved. Cutaneous telangiectases occur mainly in the exposed areas including the ears, the bridge of the nose, and the butterfly area of the face. Eventually other sites including the neck, hands, feet, and the antecubital and popliteal areas may become

involved. In some patients, mask-like facies and sclerodermatous changes develop. The telangiectatic vessels are derived from the subpapillary venous plexuses of the skin and the conjunctival connecting venules. Other cutaneous manifestations include pigmentary disturbances such as partial albinism, malignant lesions, and infections.

*Sinopulmonary infections*<sup>82,83,88</sup> are common but not invariable components of the syndrome. Children with this complication usually suffer from progressive bronchiectasis and eventually die of resultant respiratory insufficiency and sepsis. The infections usually are due to common bacterial pathogens, but do not respond well to antibiotic therapy. The increased susceptibility to infections is due to a variably associated immune deficiency that may involve defects in cellular immunity, as well as low levels of secretory immunoglobulins in secretions and in the blood.<sup>82,83,89,90,93</sup> Approximately 60% of all the patients eventually develop IgA deficiency, but according to some investigators<sup>82</sup> the associated lack of IgE, rather than the absence of IgA alone, correlates best with increased susceptibility to sinopulmonary disease. Others have found no such correlation.<sup>86</sup>

Cancer occurs with inordinate frequency in children with ataxia telangiectasia; in at least 10%, death is due to malignant lesions of various types.<sup>9</sup> Tumors of lymphoreticular origin are most common and include reticulum cell sarcomas and other lymphomas and leukemia, but tumors such as gliomas, medulloblastomas, ovarian tumors, and gastric adenocarcinomas also have been described.<sup>9</sup> Probably the most provocative characteristic of this group of malignant diseases is the fact that in six families more than one sibling with ataxia telangiectasia developed the same type of cancer.<sup>9</sup> Gonadal dysgenesis almost bordering on agenesis is also a common associated defect.<sup>88</sup>

### Inheritance

Ataxia telangiectasia is inherited as an autosomal recessive characteristic.

### Immunologic Findings

1. Lymphocyte counts are variable, and in perhaps a third of all these patients the counts are below  $1.0 \times 10^9/l$ . Plasma cells usually are present, but their numbers may be greatly reduced on occasion.

2. IgG levels are low in one third and serum and secretory IgA levels are low in about three quarters of all the patients. Whereas IgE levels also are very low in some,<sup>46</sup> IgM levels are elevated in about three quarters of all patients. Low IgM levels are extremely rare. Antibody responses generally are poor, especially in patients with IgG deficiency.

3. Cellular immune responses are grossly abnormal in most subjects<sup>88</sup>; about three quarters of these patients show no delayed hypersensitivity to naturally acquired infections such as candidiasis and cannot be sensitized to contact vesicants such as DNCB. In addition, attempts to transfer delayed hypersensitivity reactions passively from a normally responding individual generally have failed. In one study, none of the patients could reject skin homografts normally. Since patients with ataxia telangiectasia have been known to recover normally from various types of viral infections, their cellular immune responses must have been intact for a time at least.<sup>41</sup> In vitro responses of lymphocytes to PHA, allogeneic cells, and previously encountered antigens are markedly depressed.

### Pathology

At postmortem examination the thymus is almost invariably found to be small and devoid of lymphocytes; most cells appear to be of an epithelial stromal type and Hassall's corpuscles are consistently absent.<sup>88</sup> Lymph node structure has ranged from normal to almost total depletion of thymus-dependent areas and, less frequently, of follicles.<sup>88</sup>

### Prognosis and Treatment

Prognosis in this disease is poor. The ataxia and telangiectasia become progressively

worse and by the time these patients reach their mid to late teens, most of them are confined to a wheelchair. Those with recurrent sinopulmonary sepsis usually develop bronchiectasis and eventually die of respiratory insufficiency and pneumonia. A few patients survive into the third decade of life, usually with severe neurologic disability but with few respiratory complications. Many die with lymphoreticular malignant disease.

Treatment generally is inadequate. In addition to general measures described for patients with sex-linked agammaglobulinemia (page 1381), plasma infusions are used by some physicians.<sup>81</sup>

## Immunodeficiency with Thrombocytopenia and Eczema (Wiskott-Aldrich Syndrome)<sup>98,99,101,102,103,110</sup>

### Clinical Manifestations

The Wiskott-Aldrich syndrome is characterized by a triad of clinical findings: (1) recurrent infections with a variety of organisms, due to selective deficiencies of cellular and humoral immunity; (2) moderate to severe chronic thrombocytopenia; and (3) eczema. More than 100 patients with this deficiency have been described.

The primary defect appears to consist of an inability to respond immunologically to polysaccharide and lipopolysaccharide antigens (see below). Affected individuals therefore suffer from severe gram-positive and gram-negative bacterial sepsis which may involve every organ system of the body. Defects in cellular immunity lead to infections with viruses, fungi, and *Pneumocystis carinii*. Viral infections may be overwhelming and are often due to the herpes simplex virus and other viruses ordinarily associated with a benign clinical course.

Thrombocytopenia is found in all patients and may be severe. Bleeding manifestations are common and frequently are aggravated by sepsis and the use of drugs that interfere with platelet function (Chapter 35).

The eczema has the characteristics of atopic dermatitis of infancy and can be favorably influenced by topical or systemic steroids. However, such therapy is dangerous and generally unwarranted, since it undoubtedly increases susceptibility to infection. These patients also develop other allergic manifestations with unusual frequency; many are asthmatic, some develop skin-sensitizing antibodies to common allergens, and others have had food allergies.<sup>102</sup> IgE levels are very much above normal in many of these patients.<sup>46</sup> Unusually severe local and systemic reactions to the injection of sterile bacterial vaccines also have been observed. Some patients develop transient episodes of recurrent arthritis, usually involving several joints.<sup>101</sup> The cause of this process is unknown.

Patients who do not succumb to infections or bleeding due to thrombocytopenia frequently develop various forms of lymphoreticular malignant lesions,<sup>9,111</sup> including malignant reticuloendotheliomas, reticulum cell sarcomas, and other forms of lymphomas. Occasionally tumors of nonlymphoreticular origin also occur. It is estimated that death is due to malignant disease in 10% of patients with the Wiskott-Aldrich syndrome. With better general pediatric care and consequent longer survival the incidence may rise.

In addition to the physical findings discussed above, marked "benign" lymphadenopathy is a striking feature of this disease. It may be aggravated by the systemic administration of gamma globulins.<sup>9</sup>

### Laboratory Findings

1. Lymphocyte counts are normal initially, but lymphopenia is characteristically present late in the disease. This is predominantly due to a selective loss of small, thymus-dependent (or T-) lymphocytes. Plasma cells are readily found.

2. IgG and IgA levels often are increased,<sup>100,101</sup> and normal levels of IgA and its "transport piece" (Chapter 7) are found in secretions. Serum IgE levels are markedly elevated,<sup>112</sup> but IgM levels regularly are low.<sup>100,101</sup> Hypercatabolism of IgM as well

as of the other immunoglobulins and albumin has been demonstrated,<sup>100</sup> but while increased synthetic rates more than compensate for the increased catabolism of IgG and IgA, this is not the case with IgM. In addition, antibody production to polysaccharide antigens such as blood group substances, Forssman antigens, Vi antigen, and pneumococcal polysaccharides is characteristically poor or absent and antibodies to such antigens are often predominantly of the IgM type. Antibody production to protein antigens often is normal.

3. The thymus-dependent system develops normally for a time, but defects in cellular immunity soon become apparent. Thus, when first tested, most individuals with the Wiskott-Aldrich syndrome have constant defects in cellular immunity. Delayed hypersensitivity reactions to *Candida*, mumps, streptokinase-streptodornase, and similar antigens are negative and primary sensitization to contact allergens such as DNCB is difficult or impossible. Allogeneic skin grafts survive long or indefinitely. In vitro response of lymphocytes to PHA is clearly normal, but the response to specific antigens is poor.<sup>107,108</sup>

4. Neutrophils respond well to chemotactic stimuli, and phagocytose, degranulate, and kill microorganisms normally. The reticuloendothelial system clears particulate matter in normal or accelerated fashion. The complement system is normal.

5. Thrombocytopenia is found in all patients and may range from under 10 in severely affected individuals to 50 to  $60 \times 10^9/l$  in others. Platelets show some degree of anisocytosis with a few large forms but most are of a smaller than normal size. Megakaryocytes are numerous in bone marrow preparations. Platelets from normal individuals survive normally in patients with the Wiskott-Aldrich syndrome, but the half-life of autologous platelets is drastically reduced.<sup>97</sup> In addition, it was found that platelets from patients with the Wiskott-Aldrich syndrome fail to aggregate with epinephrine and no increase in citric acid cycle activity took place on addition of polystyrene-latex particles<sup>104</sup>; in this study these reactions were also found to be depressed in the mother of

the affected siblings.<sup>104</sup> Thus thrombocytopenia in the Wiskott-Aldrich syndrome may, at least in part, be due to an "intracorpusecular" defect. Similar defects have not yet been convincingly demonstrated in the skin or lymphocytes of affected individuals.

## Pathology

The thymus is structurally normal but may show some degree of involution due to stress. Germinal centers and plasma cells are abundant in the spleen and lymph nodes. With time, there is progressive depletion of small lymphocytes from the paracortical (thymus-dependent) regions. Reticulum cell hyperplasia frequently becomes evident in lymphoreticular tissues and the amount seen may correlate roughly with the age of the patient and the degree to which the patient has suffered from infections.<sup>101</sup>

## Prognosis and Treatment

Most boys with the Wiskott-Aldrich syndrome die during early childhood. The mean age at death in one study was  $3\frac{1}{2}$  years<sup>101</sup>; very few patients survive past puberty. Patients usually die of infection, hemorrhage, or lymphoreticular malignant disease, the percentage due to each cause decreasing in the order listed.

Until recently, therapy consisted of antibiotic administration, pulmonary hygiene, platelet transfusions, and plasma infusions. Because blood transfusions carry the risk of severe graft-versus-host disease once defects of cellular immunity have developed, it is imperative that all blood products be irradiated with 3000 rads before infusion. More recently, bone marrow transplantation has been tried,<sup>96,105,106</sup> but its effect does not seem to be as clearly helpful as that of transplants in patients with lymphopenic immunologic deficiency (see page 1390). Nevertheless, it may decrease the requirements for platelet transfusions and the frequency of infections. Similar changes in the immune status may be achieved in some patients by the repeated injection of leukocyte dialysates from normal donors,<sup>6a,103,109</sup> presumably because these

preparations contain "transfer factor" (see Chapter 7). In responding patients there is a decreased incidence of infections, and the number of circulating T-cells is increased.<sup>6a, 113</sup> In addition, platelet levels may rise and the eczema may disappear.

## Severe Combined Immunodeficiency (SCI)

(a) Autosomal Recessive (Swiss Agammaglobulinemia)<sup>135, 139, 140, 142, 151, 160</sup>

(b) Sex-Linked (Thymic Alymphoplasia)<sup>133, 139, 142, 158, 160</sup>

(c) ?Sporadic<sup>140</sup>

### Clinical Manifestations

The term "severe combined immunodeficiency" (SCI) describes a condition characterized by an almost total lack of antibody production and cellular immune function.<sup>128</sup> Autosomal recessive and sex-linked inheritance patterns are recognized. These had previously been designated "Swiss agammaglobulinemia" and "thymic alymphoplasia," respectively. The clinical manifestations of both of these conditions are similar although patients with the sex-linked form of the disease tend to be less severely depleted of lymphocytes and probably live longer than do patients with the autosomal recessively inherited variety.<sup>140</sup> A sporadically occurring form of the disease has been postulated,<sup>140</sup> but available pedigree analyses are insufficient to establish nongenetic mechanisms. The basic immunologic defect in severe combined immunodeficiency probably is at the level of the lymphoid stem cell and is expressed as absent B- and T-cell function.

Babies with SCI usually appear healthy at birth and start to gain weight normally. However, within the first few weeks of life they begin to develop infections of the skin, the bronchopulmonary tree, and the gastrointestinal tract and from then on infections remain with these patients for the rest of their brief lives. As a result, the clinical course is characterized by repeated bouts of pneumonia, otitis media, pyoderma, meningitis, gas-

troenteritis, and septicemia due to low-grade pathogens or more aggressive bacteria. Candida infection of the respiratory and intestinal tracts develops in almost all patients and frequently leads to systemic dissemination. In addition, affected babies are highly susceptible to viral infections of all kinds and death may follow exposure to varicella, rubeola, or vaccinia. A fulminating, rapidly fatal form of hepatitis similar to that in patients with infantile sex-linked agammaglobulinemia (page 1379) makes plasma infusions from poorly screened donors especially dangerous.<sup>41</sup> Death may also result from disseminated fungal infections, BCG vaccinations,<sup>120</sup> or *Pneumocystis carinii* infections. Thus patients with severe combined immunodeficiency are highly susceptible to all forms of pathogens.

With the onset of infections the infant fails to thrive and soon becomes extremely thin and emaciated with lax folds of skin enveloping a bony frame. The wasting syndrome is akin to that seen in neonatally thymectomized mice and could probably be prevented by raising the baby in a germ-free environment. Skin rashes develop frequently and may resemble morbilliform exanthema or what looks like full-blown atopic dermatitis. Sometimes the hemolytic uremic syndrome or disseminated intravascular coagulation develops terminally.

### Immunologic Findings

1. The peripheral blood lymphocyte count is invariably low in the sex-linked form and very low in the autosomal recessive form. There are very few lymphocytes in the lymphatic channels, lymphoid organs, and the bone marrow, although occasional nests of lymphocytes may be present in patients with the sex-linked variety of severe combined immunodeficiency.

2. Once maternal immunoglobulins have disappeared, all immunoglobulin classes are absent or extremely deficient. No secretory immunoglobulins are found with the exception of elevated IgE levels in occasional patients.<sup>46</sup> Antibody production is absent or extremely deficient. Severe depression of the

Clq component of complement has been observed, especially in the autosomal recessive form of the disease.<sup>24</sup>

3. Cellular immune responses are absent by all parameters; delayed hypersensitivity reactions to all antigens are negative and it is impossible to induce skin sensitivity to DNCB. Allogeneic skin grafts survive indefinitely. In vitro, lymphocytes from patients with severe combined immunodeficiency fail to proliferate in the presence of PHA or specific antigens. Since the lymphocyte response to PHA is mature at birth in normal infants, this provides a useful test for the exclusion of the possibility of severe combined immunodeficiency when this diagnosis is suspected because of family history or other reasons. Lymphocytes from patients with severe combined immunodeficiency generally do not respond in mixed leukocyte reactions, although weak responses may sometimes occur in individuals with the sex-linked form of the disease.<sup>118,130</sup> Macrophage function is normal.<sup>128</sup>

4. Other hematologic changes: The red cells are normal although eventually anemia develops because of infection or iron deficiency. Acute episodes of hemolysis have been described in at least one patient; these were due to an acute hemolytic uremic syndrome. Thrombocytopenia usually is normal, as is myelopoiesis. Occasionally pancytopenia develops terminally.

A deficiency of the red cell enzyme *adenosine deaminase* has been reported in several patients suffering from severe combined immune deficiency.<sup>124,130a,139a</sup> Parents and some relatives have lower than normal adenosine deaminase activity and may be carriers of the defect. Since the adenosine deaminase enzymes found in lymphocytes and red cells have similar properties, their activity in lymphocytes and red cells is thought to be controlled by the same gene.<sup>130a</sup> A causative relationship between abnormal lymphocyte function and adenosine deaminase deficiency has been postulated.

### Pathology

The thymus is tiny and vestigial, lacking recognizable Hassall's corpuscles and lym-

phocytes and consisting almost entirely of epithelial cells. It frequently is ectopic and may be found high up in the neck. The peripheral lymphoid tissues are severely hypoplastic; the pathologist may have difficulty in finding any lymph nodes at all. The spleen, the lymph nodes, and the gastrointestinal tract are almost totally devoid of lymphocytes and no lymphoid follicles, germinal centers, Peyer's patches, or plasma cells are found.<sup>142</sup> In some patients there is a marked proliferation of histiocytes which may mimic findings in the Letterer-Siwe syndrome.<sup>236</sup> Patients with the sex-linked form of the disease sometimes have a small amount of normally organized lymphoid tissue in the lymph nodes, spleen, and bone marrow.<sup>61</sup>

### Prognosis and Treatment

Without marrow transplantation (see below), SCI is universally fatal. The mean age at death in patients with the autosomally inherited diseases is five months; in those with the sex-linked form, ten months.<sup>140</sup> Death is due to overwhelming sepsis.

Conventional forms of treatment including antibiotic therapy, gamma globulin injections, and other supportive measures usually are of little long-term benefit. When a normal histocompatible sibling (Chapter 12) is available, bone marrow transplantation may be worthwhile.<sup>117,127,149,165</sup> One such patient received a sibling transplant at the age of six months and remained immunologically and hematologically reconstituted 2½ years later.<sup>127</sup> A successful transplant of bone marrow from an histocompatible uncle has also been reported.<sup>162</sup>

### Immunodeficiency with Short-Limbed Dwarfism<sup>129,137</sup>

Clinically and immunologically this syndrome closely resembles severe combined immunodeficiency with autosomal recessive inheritance (see above). It is, however, characterized by two additional features: lymphadenopathy and short-limbed dwarfism with ectodermal dysplasia. The nodes,

though large, are devoid of lymphocytes and are structurally similar to those characteristic of severe combined immunodeficiency. The dwarfism is distinctive for this syndrome and is not found separately or in conjunction with any other disease. Similarity has been noted between this syndrome and that occurring in children suffering from *cartilage-hair hypoplasia*,<sup>150,152</sup> although in the latter disease the immune defect appears to be mainly cellular<sup>150</sup>; gamma globulin levels are normal and patients are capable of producing antibodies to a variety of viral and bacterial antigens.<sup>150</sup>

## Variable Immunodeficiency (Common, Largely Unclassified)

4, 10, 23, 122, 141, 154, 156, 157, 159, 167

The extraordinary variability of immunologic findings makes classification of immune deficiency syndromes most difficult. The majority of immune defects cannot be unequivocally categorized; instead they are grouped under the heading "variable immunodeficiency," which includes diseases previously classified as (1) congenital non-sex-linked hypogammaglobulinemia (sporadic), (2) primary dysgammaglobulinemia of both childhood and adult life, and (3) acquired primary hypogammaglobulinemia, which may actually be a generically determined disorder.<sup>122,124,136,146,164</sup> Careful analysis in affected patients will in time undoubtedly yield several homogeneous syndromes.

The term "*dysgammaglobulinemia*" has been used to describe two different clinical situations.<sup>157</sup> It has been applied to patients who have serum immunoglobulins but who are nevertheless unable to produce detectable circulating antibody on repeated antigenic challenge (immunoparesis of Giedion and Scheidegger).<sup>131,132</sup> More commonly, however, the term is used to describe an immunodeficiency characterized by the presence of one or two immunoglobulins but lack of the others. Although several combinations are possible, the most common abnormality of this type is characterized by the absence of IgG and IgA and the presence of abnormally

high levels of IgM and, sometimes, IgD. This abnormality has previously been called dysgammaglobulinemia type I, but use of this designation is to be discouraged.<sup>41</sup> Congenital and acquired forms occur. The congenital variety has been described in boys only, whereas the acquired form is found in both males and females.<sup>157</sup>

## Clinical Manifestations

In individual patients, demonstrated immunologic deficiencies correlate well with the expected clinical findings. Thus adults or children with sporadic, non-sex-linked hypogammaglobulinemia have low levels of all immunoglobulins, and produce antibodies poorly in response to antigenic stimulation. They are plagued by recurrent infections with encapsulated pyogenic pathogens such as pneumococcus, streptococcus, *H. influenza*, *Pseudomonas*, and meningococcus and many suffer from intestinal giardiasis.<sup>2a,119,124</sup> In these patients there is an even higher incidence of other complications, such as autoimmune phenomena including pernicious anemia,<sup>2a,161</sup> malabsorption syndromes,<sup>119,143</sup> and allergy,<sup>125,126</sup> than one finds in patients suffering from congenital sex-linked agammaglobulinemia. Patients with "dysgammaglobulinemia" are particularly prone to develop indolent oral ulcers and widespread infection with verruca vulgaris; almost all suffer from cyclical neutropenia and some develop hemolytic anemia and thrombocytopenia.

Patients with late-onset hypogammaglobulinemia also are quite prone to develop lymphoid malignant disease, including chronic lymphocytic leukemia, lymphosarcoma, and malignant reticuloses, as well as nonlymphoid tumors such as carcinomas, sarcomas, and epitheliomas.<sup>9</sup> These malignant tumors often occur many years after the initial diagnosis of immunodeficiency was made.

## Laboratory Findings

1. Lymphocytes are usually present in normal numbers, but there may be a variable decrease in the number of those bearing sur-

face immunoglobulins (B-cells).<sup>12,8</sup> Occasionally, however, the number of immunoglobulin-bearing cells is increased even though hypogammaglobulinemia is present.<sup>121,155</sup> In such individuals the defect may consist of a block in the differentiation of lymphocytes to plasma cells.

2. Immunoglobulin deficits are invariably present, but the class involved and the degree of change are variable. Unusual distributions of IgG subgroups have been described,<sup>166</sup> as well as abnormal ratios of kappa and lambda chains and poor fixation of complement. Antibody production is variably deficient. Patients with low IgG and IgA but high IgM frequently have very high titers of isohemagglutinins and anti-Forssman antibodies.<sup>157</sup>

3. Deficient cellular immunity is often encountered, especially late in the disease.<sup>41 149 147 163</sup> As defects in cellular immunity become apparent, *in vivo* and *in vitro* tests of lymphoid function become abnormal.

### Pathologic Findings

The pathologic findings are variable but generally predictable on the basis of clinical findings. Occasionally, striking reticular and follicular hyperplasia that may mimic that associated with "benign lymphomas" is present. Sometimes marked hyperplasia of the lymphoid tissue of the ileum and even of the colon is noted.<sup>41</sup>

## Other Congenital Disorders of Host Defense against Infections

Defects of the complement system also are associated with recurrent infections, usually involving pyogenic bacteria. These include C3 deficiency,<sup>115 116</sup> C5 dysfunction,<sup>153</sup> and defects of the alternate pathway of C3 activation in patients with sickle cell disease.<sup>143</sup> (See Chapter 7 for details of the complement system.) Inherited defects of phagocytic function are discussed in Chapter 42.

## Acquired Immune Deficiency Syndromes

### Immunodeficiency with Thymoma<sup>179,183,189</sup>

#### Clinical Manifestations

The association of thymoma with hypogammaglobulinemia was first documented by Good in 1954 and since then a considerable number of patients with similar manifestations have been described.<sup>183</sup> The syndrome is most commonly encountered in the sixth decade of life, although the first symptoms may appear anytime from the third to the eighth decade. All patients with this type of immunodeficiency had been healthy previously. Members of both sexes are affected.

The thymic tumor may be discovered on routine chest x-ray examination, often before there is evidence of an immunologic deficiency syndrome. It may be so small as to be invisible on x-ray films or it may be huge; reported weights have ranged from 40 to over 2000 g with an average of 500 to 600 g.<sup>183</sup>

Once the immune deficiency becomes established, most patients complain of severe weakness and weight loss. Almost all suffer from recurring respiratory tract diseases including sinusitis, chronic bronchitis, and pneumonia. Many subsequently develop bronchiectasis, pulmonary fibrosis, and emphysema. The most frequently encountered organisms are pneumococci, but *H. influenza*, *klebsiella*, and other organisms are also present. Other infections with manifestations such as stomatitis, pyoderma, pyelonephritis, gastroenteritis, meningitis, and septicemia have been reported. *Candida albicans* infections become particularly bothersome later in the disease. Diarrhea occurs in at least a third of all the subjects and protein-losing enteropathy is often present. Symptoms of myasthenia gravis have been reported in some of these patients.<sup>183</sup>

Benign thymomas often occur in conjunction with specific hematologic abnormalities. Thus, according to one study, 6% of all pa-

tients with thymoma suffer from pure red cell aplasia or aplastic anemia<sup>204</sup> (Chapter 56); however, in those patients who have hypogammaglobulinemia in addition to thymoma, the incidence of hematologic abnormalities, especially hypoplastic or aplastic anemia, is much higher and may reach 30%.<sup>183</sup>

### Immunologic Findings

1. Lymphocyte counts are often low initially and decline further with time, often to extremely low levels. Plasma cells are absent from the bone marrow, the lymphoid organs, and the gut.

2. Severe hypogammaglobulinemia is present in all subjects; serum IgG levels are often barely detectable while IgA and IgM usually are completely absent in patients with fully developed cases. When serum IgA is lacking, it is likely that secretory IgA is also absent since this appears to be a consistent correlation in other immune deficiency syndromes.<sup>43</sup> Humoral antibody responses to all antigens are markedly reduced.

3. Cellular immunity has not been studied as extensively as humoral immunity. Nevertheless, progressively declining peripheral lymphocyte counts and inability to manifest delayed hypersensitivity reactions to natural antigens and contact allergens such as DNFB have been reported. In addition, prolonged survival of skin allografts and poor *in vitro* lymphocyte responses have been noted.

4. Associated hematologic abnormalities include anemia, reticulocytopenia, and, occasionally, leukopenia and eosinopenia. The marrow may contain few or no red cell precursors when red cell aplasia is also present.

### Pathology

Histologically most tumors are classified as spindle cell thymomas, presumably of epithelial origin, although occasionally epithelial, lymphoepithelial, or lymphocytic tumors are described. Plasma cells are usually absent from all areas. Germinal centers are lacking in lymph nodes and elsewhere, although the paracortical, thymus-dependent areas of

nodes may contain a considerable number of lymphocytes, especially early in the disease.<sup>183</sup>

### Treatment

No specific therapy is available. General measures, as described for patients with sex-linked agammaglobulinemia, may be of some help. Removal of the thymoma does not correct the immunologic deficiencies,<sup>41</sup> although it may be helpful in the treatment of the aplastic anemia.<sup>183</sup>

### Intestinal Lymphangiectasia<sup>198,211,216,217,218</sup>

#### Clinical Manifestations

Patients with intestinal lymphangiectasia have an anatomic defect in the intestinal lymphatics which leads to loss of serum proteins and lymphocytes into the bowel.<sup>211</sup> Two types of defects have been demonstrated: (1) relatively large lymphatic fistulas emptying into the upper small intestine,<sup>198,216</sup> and (2) dilatation of the lacteals of the intestinal villi suggestive of obstruction or stenosis of major lymphatic channels.<sup>168</sup> Lymphatic fluid has been shown to leak directly into the bowel lumen of patients with intestinal lymphangiectasia. In addition to a combined immunodeficiency syndrome, peripheral edema and ascites due to hypoalbuminemia may be present. While patients with intestinal lymphangiectasia suffer from hypogammaglobulinemia and profound anergy because of lymphocytopenia (see below), they do not often suffer from serious infections,<sup>217</sup> unlike patients with severe combined immunodeficiency (page 1389).

#### Immunologic Findings

1. Moderate to marked lymphocytopenia with mean values of  $0.7 \times 10^9/1.2^{18}$

2. Moderate to severe decrease of all major immunoglobulin classes, accompanied by increased fractional catabolic rate of intra-

vascular protein due to protein loss into the gastrointestinal tract<sup>211</sup>; immunoglobulin synthesis rates only slightly elevated. Antibodies to specific antigens (eg, Vi, tularemia) are produced in normal fashion, although the maximal titers are lower than in controls.<sup>211</sup>

3. Cellular immune responses, including delayed hypersensitivity reactions to PPD, mumps, trichophyton, and *Candida* antigens, are markedly reduced<sup>217,218</sup> and allogeneic skin grafts may survive indefinitely.<sup>217,218</sup>

4. Malabsorption may lead to anemia and clotting abnormalities due to vitamin K deficiency.

### Treatment

When a major lymphatic fistula into the small intestine can be demonstrated by lymphangiography or other means, surgical repair may be possible. Patients with diffuse dilatation of lacteals in intestinal villi may respond to a low-fat diet; when they do, serum proteins return to normal levels and lymphocyte counts rise.<sup>217</sup> It is possible that similar results may be achieved with a medium chain triglyceride diet.<sup>180</sup>

## Immune Deficiency Associated with Lymphoproliferative Diseases and Other Malignant Conditions

Immune functions frequently are impaired in patients with malignant diseases. While the most striking defects are seen in association with tumors originating in immunologically active tissues, other malignant conditions can also be associated with poor immune responses. These abnormalities may be further aggravated by chemotherapy, radiotherapy, viral infections, and surgical procedures, all of which have been shown to be immunosuppressive. The clinical features of lymphoproliferative disorders and their management have been discussed elsewhere in this book.

### *Multiple Myeloma and Macroglobulinemia*

Since multiple myeloma (Chapter 52) and Waldenström's macroglobulinemia

(Chapter 53) arise in cell lines that ordinarily produce antibodies, it is not surprising that antibody production is impaired in patients with these malignant conditions. Because myeloma proteins offer no protection against infections, myeloma patients characteristically suffer from repeated bouts of sepsis, usually due to high-grade encapsulated organisms such as pneumococci. In this regard, the manifestations in patients with multiple myeloma resemble those in children with sex-linked agammaglobulinemia (page 1378). Patients with the greatest impairment in antibody production also suffer most frequently from infections.<sup>125</sup>

The immune deficiency of multiple myeloma is due to two factors: (1) defective antibody synthesis<sup>125,240,252,254,279,320</sup> and (2) increased rates of gamma globulin catabolism.<sup>308</sup> As a result, most patients with multiple myeloma have decreased levels of normal immunoglobulins, often less than 20% of those of controls.<sup>279,295</sup> Sometimes immunoglobulin levels return to normal following successful chemotherapy.<sup>256</sup> The response to primary antigenic challenge in patients with multiple myeloma is characterized by a prolonged induction time for IgM production and a more rapid switchover to IgG production than takes place in normal individuals.<sup>254</sup> In addition, peak antibody titers for IgM and IgG are much lower than are ordinarily found and they decline rapidly, due, at least in part, to the increased rate of gamma globulin catabolism in this disease.<sup>308</sup> In contrast to defective primary responses, secondary antibody responses are less severely affected in persons with multiple myeloma than they are, for instance, in those with chronic lymphocytic leukemia.<sup>125,240</sup>

Cellular immunity remains relatively intact. Delayed hypersensitivity reactions to natural, previously encountered antigens remain positive, and it is possible to sensitize these patients to new antigens such as KLH or DNCB,<sup>240,254,277</sup> although the responses may perhaps be weaker than in the normal person.<sup>251</sup> The rejection time for skin allografts is often delayed, but these allografts do not survive indefinitely.<sup>277</sup>

It has been reported that when lympho-

cytes from patients with multiple myeloma are cultured in the presence of PHA<sup>295</sup> or specific antigens, such as streptolysin O, streptokinase-streptodornase, and vaccinia,<sup>254</sup> their response to these stimuli is impaired. Other investigators have reported normal responses to PHA.<sup>260</sup>

Thus patients with multiple myeloma have marked defects in primary antibody production, less severe defects in secondary antibody production, and only moderate impairment of cellular immunity.<sup>249</sup>

Patients with Waldenström's macroglobulinemia suffer from defects in both primary and secondary antibody production,<sup>125,191,290</sup> but do not develop infections as readily as do patients with multiple myeloma. The response of lymphocytes to PHA is markedly impaired.<sup>295</sup>

### Hodgkin's Disease

One of the most striking immunologic features of advanced Hodgkin's disease is lymphopenia.<sup>223</sup> This generally is a poor prognostic sign carrying in its wake progressive deterioration of cell-mediated immune responses. Terminally the condition of these patients may be similar to that of children with thymic hypoplasia (page 1384). The loss of T-cell function is a progressive one that changes and deteriorates with the advancing disease process. Thus, in early localized disease, lymphocyte counts often are normal, and the incidence of positive delayed hypersensitivity reactions to commonly encountered antigens, while lower than normal, is still considerable.<sup>224,234,273</sup> Similarly, many patients with localized disease can be sensitized to contact allergens such as DNCB,<sup>234</sup> although this has been disputed.<sup>224</sup> As the disease becomes more generalized, there is a higher incidence of unresponsiveness to previously encountered antigens,<sup>270,273,307</sup> and sensitization to DNCB becomes more difficult or impossible.<sup>224</sup> Primary sensitization with BCG or other protein antigens becomes equally unsuccessful.<sup>237</sup> In addition, passive transfer of delayed hypersensitivity reactions by the use of sensitized lymphocytes from normally reactive donors becomes impossi-

ble.<sup>12,237,270,271,287</sup> This may perhaps be related to the presence of an antilymphocyte factor in the plasma of patients with Hodgkin's disease.<sup>248</sup> Indeed, some workers have demonstrated that B cells from patients with Hodgkin's disease produce large quantities of IgG with specificity for homologous peripheral blood lymphocytes.<sup>240a,277a</sup> It has been postulated that this phenomenon may be responsible for the observed immunologic defects in Hodgkin's disease.<sup>240a</sup> Skin allografts<sup>247,271</sup> and allogeneic bone marrow grafts<sup>230</sup> often survive for prolonged periods in patients with active Hodgkin's disease.

Since cellular immunity may be impaired in patients with nearly normal lymphocyte counts, it is quite unlikely that the anergy so characteristically present in patients with Hodgkin's disease is due to lymphocytopenia alone. Thus, when lymphocytes from persons with Hodgkin's disease are transferred into the skin of a normal recipient,<sup>246</sup> the expected local graft-versus-host reaction is very poor when compared to the effect of normal lymphocytes,<sup>224</sup> suggesting that lymphocytes from patients with Hodgkin's disease are intrinsically defective, even when removed from their native environment.

The lymphocytes of patients with Hodgkin's disease also do not respond normally in vitro to phytohemagglutinin, allogeneic cells, or antigen to which they have been exposed previously,<sup>222,224,234,251,262,311</sup> but care must be taken in the interpretation of these tests since their outcome is influenced by factors other than disease activity, such as radiotherapy and chemotherapy.<sup>251</sup> In addition, a factor found in the plasma of persons with Hodgkin's disease may have an inhibitory effect on lymphocyte function in vitro.<sup>311</sup>

Macrophage function is probably normal in patients with Hodgkin's disease<sup>231</sup> and reticuloendothelial phagocytosis appears to be increased.<sup>302</sup> The ability of neutrophils to kill ingested *Candida albicans*<sup>276</sup> may be decreased.

Antibody production is impaired in patients with advanced disease, but the deficit is never as pronounced as that of cellular immunity.<sup>225,234,237,296</sup> In patients with severe generalized disease, primary immuniza-

tion may lead to lower peak titers, and these may be poorly maintained.<sup>260,294</sup> In addition, the onset of detectable antibody production may be delayed and the switchover from 19S to 7S antibody formation may not occur.<sup>260</sup> Apparently, secondary antibody responses are relatively intact, even when the same antigen fails to elicit delayed hypersensitivity reactions.<sup>229</sup> Because of decreased antibody formation, hypogammaglobulinemia sometimes develops in later stages of the disease.<sup>312</sup>

Patients with Hodgkin's disease are prone to develop tuberculosis, cryptococcosis, and certain fungal and viral infections,<sup>227-270</sup> all of which are primarily controlled by cellular immunity.

### *Non-Hodgkin's Lymphoma*

Detailed studies of immune function comparable to those for Hodgkin's disease are not available for most other lymphomas.

Patients with *lymphosarcoma* may have impaired primary and secondary immune responses<sup>229-256,296</sup> and hypogammaglobulinemia may develop late in the course of the disease.<sup>280</sup> Delayed hypersensitivity reaction to microbial antigens is impaired and becomes more marked as the disease progresses.<sup>273</sup> skin allograft rejection time is prolonged,<sup>280</sup> and the *in vitro* response to PHA is depressed.<sup>289</sup> Phagocytosis generally is intact.<sup>249</sup>

Patients with *reticulum cell sarcoma* sometimes have hypogammaglobulinemia,<sup>280</sup> cutaneous anergy,<sup>257-289</sup> and delayed rejection of foreign skin grafts.<sup>280</sup> Their *in vitro* response to mitogens is often,<sup>257-289</sup> but not always,<sup>228</sup> impaired and their lymphocytes survive poorly in culture.

In patients with *Kaposi's sarcoma*, humoral and/or cellular immune responses may be impaired.<sup>240b,278</sup>

In those with *Burkitt's lymphoma*, immunoglobulin levels may be low.<sup>239-286,319</sup> In African subjects,<sup>319</sup> but not in American ones,<sup>239</sup> impaired primary antibody formation has been found. Cellular immunity generally is normal<sup>239-318,319</sup> except in patients suffering from disseminated disease.<sup>310</sup>

### *Chronic Lymphocytic Leukemia*

Small lymphocytes from patients with chronic lymphocytic leukemia (CLL) may be either normal or abnormal (leukemic). These populations of cells can be identified and separated by a number of laboratory techniques.<sup>252</sup> In CLL the clone of malignant lymphocytes is usually derived from B cells,<sup>316</sup> but a few cases of T-cell CLL have been described.<sup>242a,291a</sup> It is therefore not surprising that the most common immunologic defect in CLL is an impairment in antibody production; occasionally defects in cellular immunity can also be demonstrated (see below).

Hypogammaglobulinemia and agammaglobulinemia are frequent accompaniments of CLL.<sup>210,267,281,291,294</sup> especially in long-term survivors and in patients whose disease is widely disseminated.<sup>314</sup> With present modes of therapy the process is probably irreversible. IgM and IgA levels appear to be affected more readily than IgG levels<sup>210,297</sup> and good correlation between the degree of hypogammaglobulinemia and frequency of bacterial infections has been established.<sup>291,301</sup> Both primary and secondary antibody responses are severely impaired,<sup>240,291,301</sup> and, while patients with higher gamma globulin levels usually show better responses than those with low levels, the response of both groups is abnormal. The primary immune response in CLL is characterized by a prolonged induction time for IgM-antibody production and a delayed switchover to IgG production.<sup>290</sup>

Delayed hypersensitivity reactions to commonly encountered antigens remain intact in most patients with CLL.<sup>222,240,291,301</sup> Many of these patients can also be sensitized to DNCB,<sup>332</sup> but generally poor responses to related chemicals such as DNFB have also been reported.<sup>240</sup> Reactivity to DNCB may be transferred by lymphocytes from reactive to nonreactive patients.<sup>232</sup> DNCB nonreactors generally appear to suffer from more advanced disease than do reactors.<sup>232</sup> Some patients are unable to reject skin allografts normally.<sup>282</sup>

The leukemic lymphocytes in CLL respond poorly to general and antigenic stimulation in culture.<sup>288,303</sup> Not only is the peak response delayed, but it is also below normal.<sup>233,293</sup> The defect is most pronounced in patients with high lymphocyte counts<sup>288,293</sup>; improved responses are noted following successful therapy and lowering of lymphocyte counts.<sup>233,300</sup> Other abnormalities of cultured lymphocytes include slow formation of new ribosomes,<sup>293</sup> abnormal RNA patterns in stimulated cells, and delayed induction of RNA methylases.<sup>252</sup> Morphologic and electronmicroscopic differences have also been reported.<sup>252</sup>

Thus patients with chronic lymphocytic leukemia suffer mainly from deficits in humoral immunity and to a lesser degree from impaired cellular immunity. In view of this combined abnormality it is not surprising that new neoplasms develop in over one third of patients with CLL.<sup>264</sup>

### Acute Leukemia

Immunoglobulin levels are usually normal in patients with acute leukemia,<sup>252</sup> although unusually high levels have been reported in juveniles with myelomonocytic leukemia in whom there is a frequent tendency to homogeneity and light chain imbalance.<sup>235</sup>

Primary and secondary antibody production usually are normal<sup>241,256,274,303</sup>; changes from normal are generally attributed to the effects of therapy.<sup>231,272</sup> Often there is recovery of immunocompetence between courses of therapy.<sup>258,259</sup> Cellular immunity is intact in many of the patients<sup>211</sup> and when it is depressed during remission-induction therapy it may also be regained between treatments. The same is true for in vitro lymphocyte responsiveness to PHA.<sup>258</sup> When defective immune responses can be demonstrated, they often indicate a poor prognosis. On the other hand, a good clinical response to chemotherapy correlates well with normal delayed hypersensitivity prior to therapy, good in vitro responses of lymphocytes to PHA, and the ability to become sensitized to new antigens.<sup>261</sup> In addition, patients who

convert from immunoincompetence to competence with therapy tend to achieve remission, whereas those converting from immunocompetence to incompetence do not.<sup>261</sup> More recent studies have shown that a good prognosis also is correlated with the ability of lymphocytes to respond to autologous leukemia cells by proliferation in vitro, as well as with the presence of IgG bound to the surface of leukemic cells,<sup>250</sup> presumably representing antibody against malignant cells. Thus, in leukemia<sup>250,261,272</sup> as in solid tumors and lymphomas,<sup>238,242,306</sup> the patient's state of immunocompetence appears to be an important factor in determining the prognosis.

### Nonlymphoid Malignant Disease

In the early course of their disease, patients with solid tumors usually have normal cellular immunity,<sup>255</sup> but, as the disease progresses, general defects in cell-mediated immune functions become evident. These may include lymphocytopenia,<sup>317</sup> poor delayed hypersensitivity reactions,<sup>263,268</sup> decreased ability to reject implants of cancer cell lines,<sup>309</sup> and weak responses in lymphocyte transfer tests.<sup>255</sup> The response of lymphocytes to PHA and other stimulants in vitro may also be depressed.<sup>245,315</sup>

There appears to be good correlation between intact cellular immunity and prognosis.<sup>185,242</sup> In addition, recovery of immune functions following therapy is an omen of good prognosis and responsiveness to further therapy.<sup>238,253</sup>

For a discussion of specific tumor immunity, see page 329.

### Sarcoidosis<sup>237,265,266,275</sup>

Boeck's sarcoid, like early Hodgkin's disease, results in a puzzling dichotomy characterized by highly selective loss of the delayed type of immune response in the presence of normal serum antibody production. The anergy was originally thought to represent an exclusive impairment of tuberculin hypersensitivity, but has since been shown to involve all forms of cellular immune functions.<sup>237,265</sup>

Delayed hypersensitivity reactions to commonly encountered antigens are clearly deficient in many patients with active sarcoidosis,<sup>237,243,265</sup> but anergy in these patients is at least partially dose dependent, since higher doses of antigen will make responders out of many previously "anergic" patients.<sup>237</sup> Similarly, the use of "depot tuberculin," or the administration of steroids either systemically or at the test site, significantly increases the number of reactors among patients with sarcoidosis<sup>237</sup> but does not increase the number of reactors in the general population. Thus, anergy in sarcoidosis is a relative matter unlike the anergy of Hodgkin's disease, which cannot be improved by these procedures.<sup>237</sup> Sensitization with contact allergens such as DNCB is also impaired,<sup>237,265,269,299</sup> but responsiveness becomes nearly normal when more powerful sensitizers such as pentadecyl catechol, an extract of poison ivy, is used.<sup>265</sup>

It is possible to transfer specific delayed hypersensitivity reactions from normal individuals to anergic sarcoid patients by injecting peripheral white cells from sensitized donors intradermally and skin testing at the same site some time later.<sup>313</sup> Generalized sensitization cannot be demonstrated by this technique and reactivity is rather short-lived. Patients with Hodgkin's disease cannot be passively sensitized by similar<sup>237</sup> or other techniques (see above). Lawrence<sup>275</sup> has been successful in transferring local reactivity by injecting dialyzable extracts of leukocytes, presumably containing "transfer factor" (see page 324), but systemic sensitization resulted in only two of seven patients. He suggested that the anergy of sarcoidosis may be due to decreased production of transfer factor or faulty transmission of the message it conveys.<sup>275</sup>

Lymphocytes from patients with active sarcoidosis respond poorly to stimulation by PHA in vitro.<sup>262,263,299</sup> Intermediate activity is seen when patients are in clinical remission.

The level of anergy can fluctuate. Thus conversion from an originally positive status to one of nonreactivity may take from two to eight months as the disease develops.<sup>237</sup> Conversely, reversion to tuberculin reac-

tivity has been observed upon spontaneous remission of the disease or after therapy.<sup>237</sup>

Elevated serum globulins are found in a third of patients with sarcoidosis<sup>265</sup> and circulating antibody production is either unimpaired or even better than normal.<sup>237,265</sup>

## Disorders Primarily Involving the Spleen

### Causes of Splenomegaly

### Chronic Congestive Splenomegaly

### Concept of "Hypersplenism"

### Methods of Evaluating Suspected Splenomegaly

### Indications for Splenectomy

**I**n the preceding chapters a number of conditions have been considered in which enlargement of the spleen occurs. There remain several that have not as yet been discussed systematically. The following pages are devoted to a classification of splenomegaly, discussion of those disorders of the spleen that have not been considered elsewhere, and consideration of methods that are useful in evaluating splenomegaly. Indications for splenectomy also will be summarized.

### Frequency of Splenomegaly and Its Significance

How important is the finding of a spleen that is just palpable on physical examination? This and questions concerning the frequency of palpable spleens and their significance are raised from time to time. In one large series of 2274 private patients seen in the United States a palpable spleen was detected in 5.6%, and in 41% of these no adequate explanation was uncovered.<sup>2</sup> In another series of 5880 unselected clinic patients, only 2% had a palpable spleen and in 25% of these no cause

was found.<sup>5</sup> Unfortunately, in these two series, no follow-up was reported. In a group of 2200 students entering college, however, spleens were palpable in 2.86% and in about 30% of these the spleen was still palpable three years after initial detection.<sup>3</sup> No evidence of increased prevalence of disease was found among members of this group.<sup>3</sup> In contrast, in certain tropical countries an incidence of splenomegaly as high as 60 to 70% has been reported.<sup>4,5</sup>

Although a palpable spleen is not necessarily enlarged<sup>1</sup> and an enlarged spleen may have no serious significance, splenomegaly may be the first and only sign of disease. Therefore, it is good practice to regard a palpable spleen as a physical sign of importance and to make an effort to discover the cause. Methods for assessing splenic size and evaluating the significance of a palpated spleen are described on page 1419.

### Causes of Splenomegaly

An enumeration of the causes of splenomegaly touches practically all the types of disease to which man is heir: infectious, metabolic, circulatory, endocrine, and neoplastic, as well as purely mechanical disorders (Table 45-1). The relative frequency of these disorders as a cause of splenomegaly differs with geographic locale, socioeconomic conditions, and other factors. Thus, even in two large series from the United States, the types of

disease associated with splenomegaly differed considerably.<sup>2,5</sup>

The ensuing discussions follow the classification outlined in Table 45-1.

# 1. Inflammatory Splenomegaly

A. The "acute" enlargement of the spleen ("acute splenic tumor") that develops in association with various infections or inflammatory processes is thought to result from an increase in the defensive activities of this organ. Increased need for clearance of particulate matter from the blood (bacteria, protozoa, damaged cells, etc.) may lead to increased numbers of reticuloendothelial cells in the spleen and/or stimulate antibody production with resulting lymphoid hyperplasia. The functions of the spleen were discussed in Chapter 8.

B. Of the infectious causes of splenomegaly, those that are chronic in nature are of chief interest here since their clinical picture may resemble that of various hematologic disorders.

1. *Tuberculous splenomegaly*, so-called "primary tuberculosis of the spleen," is a very rare condition and may be confused with tuberculosis of the spleen accompanying generalized tuberculosis.<sup>11,12</sup> About 100 cases of presumed primary tuberculosis of the spleen with splenomegaly have been reported.<sup>10</sup> The symptoms include weakness, lassitude, loss of weight, a variable amount of fever, enlargement of the spleen, which may be very great, and, in some cases, hematemesis, ascites, jaundice, and purpura. Anemia and leukopenia are the most common blood changes, but there may be thrombocytopenia as well, or thrombocytopenia may occur alone; even polycythemia has been reported.<sup>11</sup> Normoblasts may be found in the blood smear in the absence of anemia. The tuberculosis may be discovered only following splenectomy performed for the treatment of what had been thought to be "Banti's disease." In most of the cases studied adequately, tuberculous lesions were found to exist elsewhere as well.<sup>13</sup> The roentgeno-

graphic demonstration of areas of calcification in the spleen is helpful in diagnosis, but such calcification has not always been evident.<sup>13</sup> In some subjects, complete relief of symptoms followed splenectomy.<sup>10</sup>

2. Splenomegaly may occur in association with syphilis, especially congenital syphilis. The clinical picture is one of splenomegaly, chronic anemia, and, usually, leukopenia. Antiluetic therapy<sup>15</sup> may or may not be helpful and, in one of the writers' patients, recovery took place only following splenectomy. Splenomegaly may also develop in patients with tertiary syphilis as the result of the formation of huge gummas<sup>16</sup> or may result from amyloidosis.

3. Splenomegaly, chronic arthritis, anemia, and leukopenia occurring in adults comprise the disease known as *Felty's syndrome*.<sup>21</sup> This syndrome resembles Still's disease of children and has also been referred to as Chauffard-Still's disease. Loss of weight and progressive weakness are manifest. Brownish pigmentation may be observed on the exposed skin. There may be generalized lymphadenopathy and the liver may be enlarged. The anemia is moderate in degree and normocytic.

Rarely severe hemolytic anemia with shortened red cell survival has been reported.<sup>23,29</sup> Leukopenia may be pronounced ( $0.8$  to  $4.2 \times 10^9$  cells/l, average 2.5 or even less) but the differential count varies. Usually there is neutropenia and lymphocytopenia, while eosinophils and monocytes may be normal or increased in number.<sup>27</sup> Neutrophil kinetic studies have demonstrated a short  $1\frac{1}{2}$  of labeled cells in the blood and subnormal marrow granulocyte reserves.<sup>20,32</sup> findings compatible with the concept that the neutropenia is due to increased cell destruction plus inadequate marrow compensation. The leukopenia was cyclic in one patient.<sup>26</sup> Asymptomatic, moderate thrombocytopenia is common. The bone marrow may show myeloid hyperplasia, "maturation arrest" with an absence of segmented neutrophils, or it may be normal.

Felty's syndrome is thought to be a variant of rheumatoid arthritis.<sup>22,27,31</sup> Splenomegaly

**Table 45-1. Classification of Splenomegaly**

- 
- I *Inflammatory splenomegaly*
    - A Acute and subacute
      - 1 Acute splenic tumor of various infections (typhoid, septicemia, etc)
      - 2 Abscess of spleen
      - 3 Infectious mononucleosis
      - 4 Subacute bacterial endocarditis
    - B Chronic
      - 1 Tuberculosis
      - 2 Syphilis, especially congenital
      - 3 Felty's syndrome, rheumatoid arthritis
      - 4 Malaria
      - 5 Leishmaniasis
      - 6 Trypanosomiasis
      - 7 Amazonian, Bengal, and American splenomegalies Histoplasmosis
      - 8 Schistosomiasis
      - 9 Echinococcosis
      - 10 Boeck's sarcoid
      - 11 Beryllium disease
  - II *Congestive splenomegaly* ( Banti's disease " " splenic anemia )
    - A Cirrhosis of the liver
    - B Thrombosis, stenosis, or cavernous transformation of the portal vein
    - C Thrombosis or other forms of obstruction of the splenic vein
    - D Less common and unrecognized causes of congestive splenomegaly
    - E Cardiac failure (occasionally)
  - III *"Hyperplastic" splenomegaly*
    - A Frankly hemolytic anemias of various types
    - B Chronic anemias with moderately increased or no increase in blood destruction
      - 1 Pernicious anemia and related macrocytic anemias
      - 2 Thalassemia, hemoglobin C disease, and combinations of Hb's C, D, E  
Lepore, or sickle cell hemoglobin and thalassemia
      - 3 Myelophthisic anemia, myelodysplasia, "aleukemic megakaryocytic  
myelosis," "agranulocytic myeloid metaplasia," etc
      - 4 Hemolytic disease of the newborn
      - 5 Systemic lupus erythematosus
    - C Thrombocytopenic purpura
    - D Benign lymphatic hyperplasia—Graves' disease
    - E Polycythemia vera
    - F "Primary splenic neutropenia," "primary splenic panhematopenia"
    - G Cryptogenic, tropical splenomegaly ("big spleen syndrome")
  - IV *"Infiltrative" splenomegaly*
    - A Gaucher's disease
    - B Niemann-Pick's disease
    - C Amyloidosis
    - D Diabetic lipemia
    - E Gargoylism
  - V *Cysts and neoplasms*
    - A True cysts (epithelial, endothelial, or parasitic; dermoids, lymphangiomas, hemangiomas, hydatid)
    - B False cysts (hemorrhagic, serous, inflammatory, degenerative)
    - C Hamartomas
    - D Leukemias
    - E Hodgkin's disease
    - F Sarcomas, primary or secondary (lymphomas)
    - G, Histiocytosis X (Schüller-Christian and Letterer-Siwe diseases)
    - H Metastatic neoplasms
-

is known to occur in 1 to 21% of persons with chronic arthritis.<sup>25</sup> The degree of rheumatoid activity is not directly correlated with the severity of the hematologic changes in Felty's syndrome. In fact, the arthritis often may have been of long duration and may have run its course and become quiescent when the syndrome has developed. Antinuclear antibodies often are found in high titer.<sup>31</sup> The splenomegaly is of mild to moderate degree (splenic weight, 260 to 2070 g, average 910) although occasionally the spleen is huge (2400 g).<sup>29</sup> Splenectomy has produced benefit (increased neutrophil counts and decreased incidence of infection) in some of the patients so treated, but the improvement is of variable duration and neutropenia may recur.<sup>20,22,30,31,32</sup> Corticosteroids are usually ineffective in relieving neutropenia.<sup>27</sup>

4. *Malaria* is a well known and common cause of splenomegaly in many tropical countries.<sup>31,38,39,43,45</sup> Patients with chronic cases<sup>38</sup> may not have jaundice even when they have substantial anemia; leukopenia and thrombocytopenia are present in a proportion of these patients.<sup>43,45</sup> Parasites may be difficult to discover. Malarial parasites harbored in the spleen are sometimes forced into the circulation by the subcutaneous injection of epinephrine. Liver biopsy may be helpful in determining the diagnosis.<sup>39</sup> The spleen is large and may be huge.<sup>40</sup> On cut section it is slate blue<sup>36</sup> and marked reticulum cell hyperplasia is noted.<sup>40</sup> The associated anemia is due largely to red cell sequestration in the large spleen as well as increased plasma volume; the red cell mass often is normal even when red cell survival is somewhat shortened.<sup>43,45</sup> A high titer of malarial antibody often is present,<sup>45</sup> and a high incidence of cold hemagglutinins with anti-i specificity has been found.<sup>41</sup> Treatment for malaria has produced benefit in some patients<sup>35,45</sup> but not others.<sup>43</sup> Splenectomy also has been beneficial, according to some reports,<sup>45</sup> but this operation is advised only for patients with disabling symptoms since even massive splenomegaly seems to be well tolerated by many subjects.<sup>43</sup> There is evidence that, in the

spleen, malarial parasites are removed from red cells by "pitting."<sup>46</sup>

5. Both the Asiatic<sup>51</sup> and the Mediterranean<sup>52</sup> or infantile form of *leishmaniasis* (*kala-azar*) produce splenomegaly of extraordinary degrees, irregular fever, anemia, and leukopenia. Lymphadenopathy may be present, even as the primary and most important symptom.<sup>50</sup> The anemia is normocytic and the leukopenia is due to a reduction in all types of cells, especially neutrophils.<sup>51</sup> The urobilinogen content of the urine is increased. The diagnosis is made by the demonstration of the protozoan, *Leishmania donovani*, by means of splenic or bone marrow puncture<sup>51,52</sup> (Fig. 45-1).

6. In both the African and the American forms (Chagas' disease) of *trypanosomiasis* the spleen is usually enlarged, but rarely is the enlargement pronounced.

7. A clinical picture resembling that of kala-azar has been observed in the region of the Amazon River in South America<sup>50</sup> and in Bengal (India)<sup>36</sup> as well as in Central America and the United States. *Bengal splenomegaly* is attributable to a number of factors, including malaria, malnutrition, post-necrotic cirrhosis of the liver, and, ultimately, the development of portal hypertension.<sup>53</sup> The *American splenomegalies*<sup>55</sup> have been ascribed to *Histoplasma capsulatum* of Darling, a fungus morphologically resembling *Leishmania donovani*<sup>57</sup> (Fig. 45-1). *Histoplasmosis* has been reported in Europe<sup>56</sup> and in Africa<sup>58</sup> as well as in the American continent.

8. Infestation with the flukes, *Schistosoma mansoni* or *S. japonicum*, (*schistosomiasis*, *Egyptian splenomegaly*) results in diffuse hyperplastic periportal cirrhosis of the liver, perisplenic vein fibrosis, and thrombosis within the splenic vein. Progressive splenomegaly is the consequence. The liver is at first enlarged, later it shrinks and ascites develops. Eosinophilia may occur in the earliest stage of the disease; anemia and leukopenia, later.<sup>62,63</sup> The symptoms are produced by the deposition of the lateral-spined ova in the proximal and distal peripheral capillaries of

Fig 45-1. 1, *Leishmania donovani* in a large endothelial cell. Obtained by sternal puncture in a patient with kala azar. 2, *Histoplasma capsulatum* from the spleen of a patient with histoplasmosis. Note the characteristic saucer shape of the fungus, engulfed by phagocytes. 3, *Toxoplasma cuniculi* from the spleen of a rabbit. Two lymphocytes and an endothelial cell are also shown. 4, *Piroplasma* in red cells (cattle). 5, *Bartonella muris* in the blood of a rat. The organism is sometimes bacilliform, sometimes coccoid.

the portal system, with resulting fibrosis.<sup>63</sup> Differentiation from other forms of splenomegaly presenting as the "Banti syndrome" depends chiefly on the demonstration of the ova in the stools. The ova are rarely found in the spleen. Schistosomiasis has been ob-

served not only in the Nile region<sup>62</sup> and in China and Japan, but also in coastal East and West Africa, throughout the Amazon Basin, and in parts of northern South America and southern Central America as well as in Puerto Rico.

9. Splenomegaly may follow *echinococcus* disease of the liver. Echinococcus cysts of the spleen are rare.<sup>70</sup>

10. In *sarcoidosis* the spleen may be slightly, moderately, or even greatly enlarged, and sarcoidosis of the spleen, with only insignificant or absent lesions elsewhere, also has been described.<sup>71</sup> In a small percentage of the 20% of patients with sarcoidosis in whom splenomegaly occurs, thrombocytopenia is found most frequently, but also hemolytic anemia, neutropenia, pancytopenia,<sup>72</sup> and splenic rupture have been observed.

## II. Congestive Splenomegaly

Congestive splenomegaly will be discussed separately (page 1412).

## III. "Hyperplastic" Splenomegaly<sup>51</sup>

Enlargement of the spleen is a frequent finding in patients with *anemia*. It is noted in those with acute anemia as well as in those with chronic anemias of various types (Table 45-1) and in some patients with thrombocytopenic purpura. It has even been reported, apparently as a result of hemolysis, in chronic phenacetin users.<sup>73</sup> As a rule, in none of these subjects does the splenomegaly assume great proportions. Small foci of extramedullary blood formation may be found in the spleens of many of these patients. In patients with *myelofibrosis* and in a number of those with *myelophthisic anemia*, splenomegaly may be the outstanding evidence of disease (Chapter 57).

The splenomegaly associated with *polycythemia vera* (Chapter 30) can also be classed under the heading of "hyperplastic splenomegaly."

Several syndromes of unknown cause are probably best classified among the "hyperplastic" splenomegalies. "Primary splenic neutropenia" was described by Wiseman and Doan as being characterized by fever, pain in the splenic region, and splenic enlargement, with essentially normal or somewhat hyperplastic bone marrow.<sup>198</sup> It has been

reported more often in females than in males and, in the few cases described,<sup>170,185,193,196</sup> the manifestations were acute, subacute, or chronic and, in one instance, recurrent. Associated infections, especially oral ulcerations, have been common.<sup>170</sup> The splenomegaly ranged from slight to marked; the spleen was palpable in 72% of one series of 25 patients.<sup>170</sup> Thrombocytopenia and hepatic dysfunction were observed in one patient.<sup>193</sup> Relief of all symptoms was reported to follow splenectomy and relapse occurred in only one of 25 subjects.<sup>170</sup> However, the duration of follow-up was not clearly stated. The removed spleens showed extreme histiocytic predominance (clasmatoctytosis), the majority exhibiting excessive phagocytosis of granulocytes. Consequently, the disorder was attributed to excessive lysis of neutrophils by the spleen.<sup>187</sup>

"Primary splenic panhematopenia"<sup>168,169</sup> and "nontropical idiopathic splenomegaly"<sup>165</sup> may be closely related to "primary splenic neutropenia" and, like the latter condition, are of unknown cause. The clinical manifestations, as reported, have been somewhat vague and variable and may have been present for a few weeks to many years. In a few subjects, they were described as recurring periodically. Complaints included lassitude, palpitation, fever, and vague aches or pains in the extremities. Oral ulceration and indolent ulcers on the lower extremities were noted in some of these patients. Splenomegaly was prominent in several series,<sup>165,180</sup> but was noted in only three of 17 of Doan's patients.<sup>170</sup> Lymphadenopathy has usually been minimal or absent, but we and others<sup>165</sup> have seen patients who were initially thought to have a lymphoma. The reticulocyte percentage was slightly or greatly increased in some patients but not in others.<sup>170</sup> There has been little or no other evidence of increased blood destruction.<sup>180</sup> Polychromatophilia or increased osmotic fragility of the red cells was sometimes found.<sup>169</sup> The bone marrow was hyperplastic. A prompt response to splenectomy was reported in 16 of 17 patients, but, in 3, relapse occurred later and after 8 to 10 years only 8 remained alive and well.<sup>170</sup> In another series,<sup>180</sup> improvement after sple-

nectomy tended to be gradual rather than immediate and complete.

For the diagnosis of primary splenic neutropenia and panhematopenia, much stress has been laid on the *adrenalin test*.<sup>169</sup> This test, however, is regarded as unreliable by most investigators.<sup>160,180</sup> Results similar to those described in patients with primary splenic neutropenia have been observed in normal individuals and even in persons who have undergone splenectomy. As to increases in the number of neutrophils following the administration of epinephrine it is now well established that these are attributable to a shift of cells from the marginal to the circulating pool of granulocytes (Chapter 6).

It is noteworthy that most cases of primary splenic neutropenia and panhematopenia were reported several decades ago when diagnostic methods were fewer and less helpful than they are now. It must be admitted, however, that cases of splenomegaly associated with neutropenia or pancytopenia which defy diagnosis are still encountered occasionally. The pathogenesis of primary splenic neutropenia and of primary splenic panhematopenia as examples of "primary hypersplenism" is discussed on page 1319.

Splenomegaly of obscure etiologic background is relatively frequent in the *tropics*. A syndrome of enlargement of the spleen, often massive, has been found among the Chinese of Hong Kong and in parts of China and Formosa ("cryptogenic splenomegaly of China").<sup>76</sup> This syndrome has been associated with varying degrees of liver damage, marked by features of both diffuse hepatic fibrosis and post-necrotic scarring. In some subjects the splenomegaly seemed to anticipate the liver changes. Abnormal vascular fragility, unrelated to thrombocytopenia, and chronic leg ulcers are additional features of this disorder. The associated anemia was thought to be due to both the destructive action of the spleen and abnormality of the red corpuscles, the latter possibly caused by the liver disease (page 708). Expanded plasma volume also contributed to the anemia. All of these manifestations were reported to respond favorably to splenectomy.

The "tropical splenomegaly" or "big spleen"

*syndrome*<sup>84,190</sup> is characterized by massive splenomegaly of uncertain cause. It is said to be found only where malaria is endemic. A history of recurring fever is common, but, once splenomegaly has developed, patients have usually been afebrile. Many have been only mildly incapacitated despite massive spleens extending into the pelvis. Anemia, attributed to increased plasma volumes and a greater splenic red cell pool, and leukopenia and thrombocytopenia are common.<sup>84</sup> Malarial infection may play an etiologic role, the syndrome possibly resulting from an atypical immune response to malaria.<sup>84</sup> Malaria chemotherapy, if continued for long periods, may result in decrease in spleen size and increase in hemoglobin level. Splenectomy has been beneficial in selected patients.<sup>84,190</sup>

#### IV. "Infiltrative" Splenomegaly

Under this designation may be grouped those instances of splenomegaly apparently resulting from excessive storage of normal and abnormal metabolic products—a cerebroside in Gaucher's disease and sphingomyelin in Niemann-Pick's disease. Perhaps gargoylism should be added here. These conditions were discussed in Chapter 42. The splenic enlargement found in amyloidosis, glycogen storage disease, and in diabetic or other forms of *lipemia* also may be added to this group of splenomegalies. In one patient with type I hyperlipoproteinemia, the spleen contained large amounts of ceroid.<sup>80</sup>

#### V. Cysts and Neoplasms

Tumors of the spleen may be benign or malignant. The benign tumors include cysts and hamartomas. Splenic cysts may be lined by a specific secreting membrane (true cysts); these are epithelial (dermoid, epidermoid), endothelial (lymphangioma, hemangioma, polycystic, serous), or parasitic (echinococcus).<sup>85</sup> False cysts may be hemorrhagic,<sup>96</sup> serous, or inflammatory, or they may be due to degenerating liquefaction of areas infarcted<sup>95</sup> by embolism or arterial thrombosis. Over 400 nonparasitic cysts have been re-

ported.<sup>92</sup> Fullness in the epigastrium, vague digestive complaints, or even epigastric pain may develop and, when the diaphragm has been elevated, dyspnea, cough, and pain radiating to the shoulder may be experienced.<sup>83</sup> The tumor may be felt in the left upper quadrant as a rounded mass that displaces the stomach downward and to the right. The splenic flexure of the colon and the left kidney may be displaced downward. Calcification is not common. Nonparasitic splenic cysts have been noted most frequently in women, especially in those of childbearing age. Their cause is unknown, but trauma has been thought to play a dominant role.

Hemangioma of the spleen does not usually produce a tumor that is detectable clinically, but it may rupture into the peritoneal cavity, in which instance the diagnosis of perforated peptic ulcer or acute appendicitis may be mistakenly made.<sup>97</sup> Hemangiosarcoma is rare and may be associated with a leukoerythroblastic blood picture.<sup>67</sup>

Hamartomas are rare benign tumors composed of abnormal mixtures of normal splenic elements.<sup>99</sup>

The splenomegaly of Hodgkin's disease is discussed in Chapter 50; histiocytosis X, in Chapter 42. Sarcomas of the spleen most often represent only one aspect of more widespread disorders (lymphosarcoma, follicular lymphoma, reticulum cell sarcoma, Hodgkin's sarcoma). These diseases are discussed in Chapter 51. Primary sarcoma of the spleen, a tumor arising from the supporting tissues of the organ, is relatively rare. In addition to a palpable mass in the left upper quadrant of the abdomen, there may be pain in this area, and fever, anemia, and general debility may be noted. More rarely, pleural effusion, gastrointestinal hemorrhage, and splenic rupture have been observed.<sup>91, 98</sup>

Of metastatic tumors, carcinoma is the most frequent type.<sup>90</sup> Although it is unusual for the spleen to be sufficiently enlarged to be palpable clinically, metastases to the spleen, from lung, breast, skin, and cervix, have been observed at autopsy in 2.3% of patients with carcinoma.<sup>80</sup> The low incidence of splenic metastases as compared with me-

tastases found in lymph nodes, liver, and lungs has been attributed to inequality of exposure. Lymphatic spread of carcinoma to the spleen has been observed.<sup>88</sup> No inhibiting effect of splenic tissue on carcinomatous growth has been demonstrated.

## Chronic Congestive Splenomegaly

("Banti's Disease," "Splenic Anemia")

### History and Definition

In 1866<sup>114</sup> the term "splenic anemia" was introduced to designate cases of anemia associated with splenomegaly which could not be classified as frank leukemia. At the end of the century, Banti<sup>101</sup> described a form of splenomegaly that was not associated with leukemia, Hodgkin's disease, or hemolytic jaundice, nor was it caused by malaria, syphilis, or other recognized diseases. He laid down clinical and histologic criteria for the recognition of the disorder and described three stages: (1) an anemic phase with splenomegaly, leukopenia, asthenia, and occasional hemorrhagic episodes; (2) a later intermediary phase in which hepatic enlargement occurred, urobilinuria developed, and a dirty, brownish discoloration of the skin sometimes appeared; and (3) a final stage of liver atrophy and ascites. The spleen was markedly enlarged and histologically was characterized by conspicuous thickening of the fibrillar reticulum. Banti considered the spleen to be the primary seat of the disease and assumed that anemia, hepatic cirrhosis, and sclerosing endophlebitis of the splenic and portal veins followed.

Osler<sup>132</sup> drew the attention of English-speaking clinicians to the condition and seemed to accept it at its face value, but many pathologists refused to endorse the concept enunciated by Banti. Dürr,<sup>108</sup> for example, showed that sections of spleens from Banti's own subjects could not be differentiated from those found in the spleen in patients with hepatic cirrhosis. Eppinger<sup>110</sup> introduced the term "hepatolienal fibrosis" to describe the

essential pathologic changes.<sup>127</sup> Later investigations of the pathogenesis of the disorder showed that this syndrome is associated with portal hypertension and led to the use of the term "chronic congestive splenomegaly."<sup>149</sup>

### Clinical Features

The concept that Banti's disease is a specific entity is now largely discredited, but the syndrome of congestive splenomegaly is recognized. The clinical features of the syndrome, as described in the early reports, were as follows.

Those affected were stated to be usually under 35 years of age, the disease occurring even in children.<sup>143</sup> Females were twice as numerous as males in Banti's series and this was true of Giffin's series,<sup>113</sup> but was not the case in all series reported.<sup>109,127</sup> A familial incidence, though unusual, was not unknown.<sup>127</sup> The onset was described as usually insidious, but might come with explosive suddenness characterized by vomiting of blood or the passage of large, tarry stools. Gastrointestinal hemorrhage occurred in about half the patients.<sup>128</sup> In others, abdominal pain or discomfort, the discovery of a mass in the left upper quadrant of the abdomen, or symptoms of weakness and general lassitude referable to anemia were the manifestations responsible for consulting a physician. Flatulence, diarrhea, vague indigestion, or even mild jaundice in association with abdominal pain and fever and a non-icteric type of sallow-brown pigmentation of the skin were described. Epistaxis occurred in about a third of the patients, but other hemorrhagic manifestations such as purpura were unusual. The spleen was described as large and might be enormous, extending even to the pelvic brim.<sup>113</sup> Moderate hepatic enlargement was observed at an early stage in perhaps a third of the subjects.<sup>104</sup> Lymphadenopathy was absent and weight loss was not conspicuous.

Splenomegaly sometimes preceded anemia<sup>113</sup> and the latter, unless hemorrhages had occurred, was at most moderate in degree and as a rule normocytic in type.<sup>104,122</sup> The average red cell count in 151 reported cases was

$3.4 \times 10^{12}/l$ . At this stage the morphologic appearance of the red cells was not remarkable. Repeated hemorrhages resulted in hypochromic microcytic anemia with all the morphologic features of this type of anemia (page 657). Following a hemorrhage the reticulocytes might be slightly or moderately increased in number and occasional normoblasts were observed. The fragility of the red corpuscles to hypotonic saline solutions was normal or reduced.<sup>128</sup> When the condition was of long standing and well marked, cirrhosis of the liver was present. Macrocytic anemia sometimes developed temporarily following an acute hemorrhage.<sup>150</sup>

Leukopenia is the most constant feature of the blood picture. Leukocyte counts less than  $5.0 \times 10^9/l$  were observed in about two thirds of the patients.<sup>113,128</sup> A curious feature of the leukopenia is that the diminution often affects all the types of cells, the ratio of the polymorphonuclear cells to the lymphocytes and monocytes remaining normal as a rule. Leukocytosis may follow a severe hemorrhage or may be associated with venous thrombosis or an acute exacerbation of hepatitis.

The platelet count is often somewhat reduced and sometimes is well below  $100 \times 10^9/l$ . The bleeding time may be prolonged.<sup>128</sup> As a rule, however, bleeding and coagulation times are normal.

Findings in the *bone marrow* on sternal puncture vary. In the earlier stages, at the time when there is little or no anemia, no abnormality may be noted. Myeloid hyperplasia in the earliest stage<sup>123</sup> and "maturation arrest" of the myeloid and megakaryocytic tissue later have been described. In the last stage in which cirrhosis of the liver is present, there may be normoblastic hyperplasia.

The relation of these changes in the blood and bone marrow to the syndrome of "hypersplenism" will be discussed shortly (page 1417).

### Course

The course of the disease was described as prolonged and often benign. Sometimes it

seemed to become arrested spontaneously, the patient living for a number of years with little or no disability. At any time, however, the uneventful course might be interrupted by one or more episodes of gastrointestinal hemorrhage, portomesenteric venous thrombosis, or hepatitis. Other patients experienced more or less steady progression of the condition, with the development of symptoms of hepatic insufficiency and the signs of portal venous obstruction. Death frequently resulted from one of the above-mentioned complications or from intercurrent unrelated disease.

### Diagnosis

Moderate anemia and leukopenia are found in association with many conditions producing splenomegaly and the presence of any of these must be ruled out before the diagnosis of congestive splenomegaly is considered. Hemolytic anemias, "aleukemic" leukemia, chronic hypochromic anemia, thalassemia, and hookworm anemia, as well as most of the other conditions listed in Table 45-1, have been mistaken for "Banti's disease." The finding of lymphadenopathy or of immature leukocytes in the blood smear favors conditions other than congestive splenomegaly. Sternal marrow examination is useful in ruling out the possibility of "aleukemic" leukemia.

Chronic congestive splenomegaly may result from any one of a variety of causes. The splenic vein may be obstructed because of thrombosis or as the consequence of compression from pancreatic fibrosis or aneurysm of the splenic artery, or by a tumor of the pancreas, such as a cystadenoma<sup>115</sup> or carcinoma.<sup>126</sup> The portal vein may be obliterated due to bland thrombosis, pylephlebitis, or from cavernous transformation, or it may be absent ("aplasia of portal vein").<sup>140</sup> The hepatic veins may be thrombosed (Budd-Chiari syndrome) and cause increased vascular resistance. The obstruction, on the other hand, may be intrahepatic and result from cirrhosis. The cirrhosis may be of the Laennec variety or may follow hepatitis or schistosomiasis. However, in a few reported cases

it was not possible to demonstrate either intra- or extrahepatic obstruction.<sup>147</sup> In these it was postulated that the portal hypertension was caused by increased blood flow through the portal vein.

Extrahepatic portal obstruction is more common in patients under 18 years of age than later in life. There are likely to be no gastrointestinal symptoms except when bleeding occurs. The liver is not palpable. Splenomegaly may be associated with the Cruveilhier-Baumgarten syndrome, which is recognized by the presence of a prominent para-umbilical vein, as well as a venous hum and a thrill at the site of the para-umbilical circulation.<sup>105,119</sup>

A variety of relatively simple procedures are available for the study of patients with congestive splenomegaly. Liver function studies obviously are necessary. It is important to note, however, that reduced Bromsulphalein excretion may be due to diminished blood flow through the liver, and that portal hypertension may be responsible for abnormal findings in other liver function tests, even when the obstruction is extrahepatic.<sup>135</sup> The extent of collateral circulation should be determined and esophageal varices looked for. The portal venous pressure may be gauged by measurement of intrasplenic pressure by means of percutaneous splenic puncture with a fine needle and a strain gauge.<sup>100</sup> Intrasplenic pressure has been found to bear a linear relationship to the portal venous pressure. Before making a decision concerning treatment, portal venography should be carried out. This may be accomplished by the percutaneous injection of the splenic pulp with radiopaque solutions,<sup>211</sup> or by direct injection of a contrast medium into the portal vein at operation.<sup>211</sup> The latter is necessary to confirm a diagnosis of anatomic obstruction, as the portal vein sometimes is not completely opacified in the percutaneous splenoportogram.

### Treatment

The chief problem is to reduce the portal hypertension and thus lessen the chance of hemorrhage. Unless this can be accomplished

the patient has little chance of survival beyond a year or two at the most.<sup>140</sup>

If iron-deficiency anemia is present due to blood loss, iron therapy (page 660) is indicated. There is no need for administration of folic acid or vitamin B<sub>12</sub>, but the diet should be nourishing and contain an adequate supply of vitamins. Severe hemorrhage will necessitate blood transfusions and balloon tamponade may be required if early severe bleeding persists.

Omentopexy,<sup>120</sup> the production of an Eck fistula, and, later, splenectomy were employed in attempts to relieve the portal hypertension. *Splenectomy* may relieve the leukopenia or pancytopenia,<sup>125</sup> when present, and is effective in relieving obstruction close to the splenic hilum, but otherwise it has not proved to be useful since little reduction in portal hypertension results. The immediate postoperative mortality has been high and hemorrhage has recurred in as many as 50% of the patients.<sup>125</sup> In a comparative study of 51 splenectomized patients and 43 who were not subjected to splenectomy, no differences between the two groups could be demonstrated in regard to life expectancy, prevention of the progress of hepatic disease or anemia, or the occurrence of hematemesis.<sup>118</sup> The implications of another study were similar.<sup>116</sup> Many surgeons believe that a splenectomy should not be attempted unless one is prepared to perform a venovenous anastomosis, since this may be the only opportunity to construct a satisfactory shunt.<sup>124,139</sup>

Disappointment with the results of splenectomy led to the introduction of *portal-systemic shunt* operations for the purpose of relieving portal hypertension.<sup>124</sup> When there has been marked splenomegaly and a large-caliber splenic vein has been available, or when the portal vein has been obliterated, splenectomy and splenorenal shunt have been recommended by some, in preference to portacaval anastomosis, because of a lower incidence of severe neurologic disturbances and ammonia intoxication.<sup>103</sup> However, portacaval shunt has been the preferred procedure, on the assumption that the use of the largest-caliber vessel available is likely to maintain a patent shunt most efficiently.<sup>140</sup>

Portal-systemic shunts are advised only: (1) in patients in whom upper intestinal hemorrhage is severe and in whom the portal hypertension is due to extrahepatic block; or (2) in patients with portal hypertension associated with cirrhosis of the liver in whom there is bleeding from esophageal varices and yet minimal or absent ascites and icterus, and a reasonable degree of hepatic reserve. When these criteria were followed, the occurrence of bleeding was markedly reduced and life was prolonged.<sup>111</sup> Operative mortality was reported to be 11% and the overall mortality 29%. There is little justification for prophylactic portal-systemic shunts.

More recent experience with side-to-side portacaval anastomosis (in contrast to end-to-side) has resulted in operative mortality of only 6 to 7%, and survival curves leveling off at about 60% after three years.<sup>102</sup> In occasional patients, however, progressive splenomegaly and cytopenia have developed after portacaval shunt operations.<sup>137</sup> The use of supradiaphragmatic splenic transplantation has been successful in the management of occasional patients having portal hypertension, especially those with hepatic vein thrombosis.<sup>144</sup> This procedure apparently results in very effective shunting of blood through anastomoses between the spleen and the pleural vessels.

Marked deposition of hemosiderin has been observed on microscopic study of cirrhotic human livers after surgical portal-systemic shunting.<sup>107</sup> Experimental studies suggest that hematopoiesis generally is depressed as a result of this procedure and that iron accumulates in the liver as a consequence.

### Pathology

As a rule the spleen weighs 600 to 1200 g<sup>127</sup> but may be as heavy as 5000 g.<sup>113</sup> The capsule is thickened and adhesions between the spleen and the stomach or diaphragm may be present. On section the spleen appears grayish-red in color and firm in consistency. The trabeculae are prominent and the malpighian bodies are inconspicuous. Fibrosis, dilatation of the sinuses, hyaline degenerative

changes in the malpighian bodies and the follicular arterioles, and periarterial hemorrhages are found on microscopic examination. Siderotic nodules consisting of crystalline and amorphous iron pigments deposited in the fibrous tissue around the arterioles are seen in many instances.<sup>127</sup>

Surgeons describe distended and tense venous radicals in the splenic pedicle and rich collateral veins enveloping the spleen, as well as great distention of the splenic vein.<sup>139</sup> Endophlebitis of the splenic and portal veins is frequent, and there may be thrombosis of these veins, stenosis or cavernous transformation of the portal vein,<sup>139</sup> or compression of the splenic vein by tumors or scars. Cirrhosis of the liver may be evident or may be discovered only at microscopic examination.

### Pathogenesis

The histologic picture<sup>81,127</sup> in the spleen, as described by Banti, is not specific but may be seen, for example, in patients with cirrhosis of the liver and in those with portal or splenic vein thrombosis. The changes are of such a nature as might easily be produced by congestion of the spleen.<sup>127</sup> The distention in the sinuses, the hemorrhages, fibrosis, and also the siderotic nodules can be explained on this basis. In addition, definite signs of portal venous congestion are usually observed. Measurements of the pressure in the splenic vein in 14 patients presenting the clinical picture of Banti's syndrome showed the pressure to range from 225 to more than 500 mm normal saline solution and was greater than 300 in 11 of the subjects.<sup>139</sup> In contrast, in 15 patients having splenomegaly of other types, such as hemolytic disease and thrombocytopenic purpura, the pressure ranged from 70 to 275 mm in 14. In another study carried out on 100 adults of both sexes in whom the possibility of hepatic and neoplastic disease had been excluded, the average portal pressure was found to be 215 mm water and ranged from 100 to 300 mm.<sup>130</sup>

Causes of portal hypertension have been mentioned (page 1414). It is recognized that

the liver may be diseased long before significant clinical evidence is found. A high incidence of hepatic abnormality (68% or more) has been reported in patients with Banti's syndrome.<sup>104,122,146</sup> Noteworthy also is the fact that splenomegaly of some degree has been found in as many as 79% of persons with cirrhosis.<sup>81</sup>

The hematologic changes in patients with Banti's syndrome are attributable to the unequal distribution of the cells of the blood in the splenic vascular bed and the remaining parts of the circulation.<sup>138</sup> This is the consequence of stasis of the portal circulation. In addition, there is increased destruction of blood cells, as will be discussed in the following section of this chapter ("hypersplenism"). The rate of removal of damaged red cells in the spleen has been found to correlate best with spleen size and poorly with portal pressure.<sup>117</sup>

No clinical or hematologic differences between patients with congestive splenomegaly due to intra- or extrahepatic obstruction have been observed, except in those with advanced liver disease. Furthermore, the histopathology of the spleen has been the same in all the patients, no matter what the cause of the portal hypertension happened to be. Following splenectomy, blood values usually have returned to normal. These observations strongly support the view that Banti's syndrome is the consequence of any of a variety of lesions producing chronic splenic vein hypertension.

Partial or complete occlusion of the portal vein<sup>129</sup> in rats and rabbits failed to produce the typical Banti syndrome. However, when hepatic cirrhosis was produced in rabbits by manganese<sup>127</sup> or in dogs by means of silica,<sup>136,141</sup> splenic enlargement and the picture of congestive splenomegaly did develop. Congestive splenomegaly also has been produced by the intraperitoneal administration of methyl cellulose<sup>112,133</sup> (page 1418).

Failure to demonstrate an obstructive factor in a number of cases and the fact that portal obstruction independent of splenic disease has been observed in the absence of appreciable splenic enlargement led to an

alternative concept<sup>136</sup> which, while accepting the significance of splenic congestion, revived the theory of "primary" splenic disease. It was suggested that the small splenic arteries play an important role in adjusting the intake of blood into the spleen. It was argued that, because of disease of these arteries, blood enters the spleen in increased quantity, leading to congestion, and this in turn causes portal hypertension and even degenerative changes in the liver cells.

## The Concept of "Hypersplenism"

### History and Definition

The concept that the "organ of mystery," as Galen called the spleen, can be a cause of disease seems plausible since this organ, which is normally not palpable, may become enlarged under certain circumstances, and then anemia, leukopenia, or thrombocytopenia or combinations thereof are not uncommonly associated. In such patients, these clinical manifestations may disappear following splenectomy.

The idea that the spleen may produce ill effects through exaggeration of its normal activities was entertained in 1866 by Gretscl and in the 1880's by Banti. In 1907, Chauffard introduced the term "hypersplenism" to refer to this concept.<sup>155,160,173</sup> However, this hypothesis did not become popular until many years later.<sup>168,169</sup> and since then there has been considerable confusion concerning the nature or meaning of the term and the pathogenesis of such a condition.<sup>162</sup> Criteria for a diagnosis of "hypersplenism" include: (1) anemia, leukopenia, thrombocytopenia, or combinations thereof; (2) cellular bone marrow; (3) splenomegaly; and (4) improvement following splenectomy.<sup>155</sup>

### Classification

"Hypersplenism" has been classified as "primary" and "secondary."<sup>155,166,173,200</sup> The

term "secondary hypersplenism" has been used in referring to cases in which some more or less well-defined disorder can be identified,<sup>155,163,166,180</sup> while "primary hypersplenism" refers to those in which an underlying disease cannot be found.<sup>155,165</sup> Thus, "secondary hypersplenism" includes a variety of infectious<sup>163</sup> or parasitic disorders<sup>190</sup> and certain storage diseases, such as Gaucher's disease, when they involve the spleen, as well as some cases of leukemia and lymphosarcoma<sup>192</sup> in which cytopenia is prominent and is relieved by splenectomy. Congestive splenomegaly (page 1412) and Felty's syndrome are also included. "Hypersplenic" syndromes have even been described in association with hyperthyroidism<sup>179</sup> and with urticaria pigmentosa.<sup>175</sup> Some have included hereditary spherocytosis, other hemolytic anemias, and idiopathic thrombocytopenic purpura as forms of hypersplenism.<sup>155,168,173</sup> Primary hypersplenic syndromes include "primary splenic neutropenia," "primary splenic panhematopenia," and "splenic anemia," discussed on page 1410.

It is true that many or all of these conditions fulfill the criteria for the diagnosis of hypersplenism listed above. Whether the use of this designation is helpful is less obvious.

### Pathogenesis

The functions of the spleen are discussed in Chapter 8. Although much still remains to be learned about this organ, it has been clearly established<sup>190</sup> that (1) an enlarged spleen may sequester large numbers of red cells, platelets, and granulocytes, which (2) may be damaged there or be destroyed; and (3) total plasma volume may increase in association with splenomegaly, resulting in some degree of "pseudo-anemia." There is, on the other hand, little evidence that humoral factors are produced in the spleen as some investigators<sup>162,194</sup> have proposed.

The pathogenesis of the hematologic changes that may be associated with big spleens has been studied with radioactive isotopic labeling techniques. Variable degrees of splenic sequestration and/or increased cell

destruction have been found.<sup>156,158,161,165,172,190</sup> Furthermore, it has been demonstrated that in patients with massive splenomegaly from a variety of causes (including nontropical splenomegaly,<sup>165</sup> tropical splenomegaly,<sup>190</sup> cryptogenic splenomegaly,<sup>76</sup> congestive splenomegaly,<sup>161,172</sup> myelofibrosis,<sup>161,172,177,181</sup> chronic lymphocytic leukemia,<sup>181</sup> and chronic myelocytic leukemia,<sup>172,181</sup> as well as other causes<sup>161,172</sup>), an apparent *anemia*, as judged by venous hemoglobin or packed red cell concentration, is often due to expansion of the plasma volume in the presence of a normal red cell mass, a significant portion of which is sequestered in the enlarged spleen.<sup>190</sup> Expansion of the plasma volume in the presence of a normal red cell mass may be detected by simultaneously measuring the red cell mass and plasma volume and by comparing the total body to venous hematocrit ratio. The latter has been found to be above the normal range of  $0.896 \pm 0.039$ <sup>177</sup> in most patients with enlarged spleens. It was demonstrated that the ratio increased progressively in direct proportion to the degree of splenic enlargement.<sup>177</sup> As much as 38% of the total red cell mass may be trapped in a massively enlarged spleen.<sup>190</sup> Reduction in red cell survival time may or may not be found,<sup>43,172,190</sup> but the anemia appeared to be due mainly to hemodilution and sequestration.<sup>161,172,181</sup> In this regard, it should be noted that hypervolemia with an expanded plasma volume and normal or only slightly reduced red cell mass plus moderate anemia has been found in patients with cirrhosis even when no striking splenomegaly was present.<sup>186</sup> It is postulated that the plasma volume in the expanded portal vascular space probably is increased. This may be the result of a marked increase in metabolism and a decrease in peripheral resistance leading to salt and water retention through the renin-angiotensin aldosterone mechanism.<sup>181</sup>

*Leukopenia and neutropenia* in association with splenomegaly appear to be due to increased destruction in some cases<sup>158</sup>; in others, sequestration may possibly play a role. Again, in association with splenomegaly as much as 50 to 90% of the total *platelet*

*mass* may be sequestered in an enlarged spleen.<sup>156</sup>

Animal experiments support the concept that abnormal blood cell sequestration and destruction occur in a hyperplastic spleen. Thus, in rats injected with methylcellulose to produce splenomegaly and anemia, transfused normal rat erythrocytes were sequestered and destroyed in the enlarged spleen.<sup>112,188</sup> In contrast, red cells from the methylcellulose-injected rats survived normally when transfused into normal animals. Thus, methylcellulose-injected rats suffered from an extracorporeal hemolytic anemia that required the presence of a hyperplastic spleen.<sup>149</sup> It is of interest that suckling offspring of hypersplenic animals also became anemic, thus suggesting that hormonal factors may have been operative.<sup>162</sup>

As understanding has grown, conditions that at one time were attributed to "hypersplenism" have been shown to be due primarily to defects in tissues other than the spleen. Thus the fault in hereditary spherocytosis rests in the red corpuscle itself. Likewise "idiopathic" thrombocytopenic purpura is attributable in most instances to antibodies and the fault does not rest primarily in the spleen. Even though the defective or damaged blood elements are sequestered and/or destroyed in the spleen and splenectomy alleviates the manifestations, application of the term "hypersplenism" to these conditions is misleading since the primary defect is not in the spleen. In regard to other conditions characterized by anemia, leukopenia, and/or thrombocytopenia in association with splenomegaly and whose cause is as yet not understood, such as "primary splenic neutropenia" and "primary splenic panhematopenia," it is reasonable to expect that in most, and perhaps all, instances the primary fault will be found in sites other than the spleen, with the spleen playing a secondary role. In this sense the term "hypersplenism" tends to hide our limited knowledge by implying a pathogenic mechanism that is imprecise and probably erroneous. Therefore, we prefer to avoid its use and wherever possible we refer specifically to such mechanisms as sequestration or destruction, or other mechanisms by which

the observed hematologic changes may be produced.

## Methods for Evaluating Suspected Splenomegaly

A palpable mass in the left upper quadrant of the abdomen, although often an enlarged spleen, may be due to other causes such as gastric, pancreatic, ovarian, or renal cysts or tumors. Appropriate studies including an intravenous pycnogram and barium swallow will usually suffice to rule out the possibility of renal and gastric pathologic conditions. The possibility of pancreatic cysts or tumors may be more difficult to exclude with conventional radiographic techniques.<sup>85</sup>

### Splenoportography

The presence of pancreatic cysts has occasionally been revealed when splenoportography was carried out in an attempt to visualize what was thought to be a large spleen.<sup>206</sup> However, splenoportography has found wide use chiefly in evaluating: (1) the patency of the portal vein and the distribution of collateral circulation prior to shunt operations for cirrhosis; (2) the cause of esophageal varices in the absence of liver disease; and (3) the cause of idiopathic splenomegaly (especially in children).<sup>100,111,208</sup> It probably should be avoided if the platelet concentration is low or if there is an increased tendency to bleed since 50 ml of blood or more are regularly found in the abdomen after this procedure<sup>208</sup> even when clotting function is normal.

### Angiography

Selective angiography is probably a safer and more useful procedure than splenoportography for differentiating splenic cysts or other abnormalities in the spleen from nonsplenic tumors.<sup>216,229</sup>

### Spleen Scans

Enlargement of the spleen as assessed subjectively by the radiologist viewing an ordi-

nary film of the abdomen is less accurate in predicting splenomegaly than is definite palpability.<sup>4</sup> Likewise, ordinary abdominal films are often unsatisfactory in that the spleen is not visualized in as many as 40% of those examined.<sup>4</sup> However, nonpalpable spleens may be enlarged, and it has been claimed that in only 30% of patients with enlarged spleens as determined by scans has the organ been palpable.<sup>222</sup>

The best noninvasive method for evaluating spleen size is the spleen scan. In 17 patients scanned 24 to 72 hours before splenectomy a close correlation between spleen length on scan and spleen weight after surgical removal was demonstrable ( $r, +0.96$ ).<sup>219</sup> In another study, spleen mass as estimated from scans was compared with spleen weight at postmortem examination. Errors of less than 12% (mean of 7%) were found over a wide range of spleen sizes (weights, 180 to 2000 g).<sup>223</sup>

Several techniques are available for spleen scanning; these include labeling erythrocytes with <sup>51</sup>Cr, <sup>197</sup>Hg, <sup>81</sup>Rb, or <sup>99m</sup>Tc<sup>210,221</sup> and mildly damaging the cells by means of treatment with heat, antibody, chemicals, or metal ions so that they will be sequestered by the spleen after infusion. More generally used are colloidal suspensions of radionuclides such as technetium (<sup>99m</sup>Tc), gold (<sup>198</sup>Au), or indium (<sup>113m</sup>In).<sup>221</sup> The relative merits of these techniques are discussed in several reviews.<sup>221</sup> In addition to assessing spleen size, spleen scans may be useful in detecting space-occupying lesions in the splenic substance<sup>221</sup> (Fig. 45-2), and in evaluating loss of spleen function, absence of the spleen, or the presence of an accessory spleen.<sup>221</sup>

### <sup>51</sup>Cr-Labeled Red Cells

Most widely used in evaluating the degree of splenic sequestration and/or cell destruction in the spleen of patients with anemia are data obtained after the infusion of <sup>51</sup>Cr-labeled red cells. The subsequent measurement of red cell mass (Chapter 3), red cell survival in the blood (Chapter 5), the rate of mixing in the spleen, and localization of label in the spleen as compared with the liver and precordium

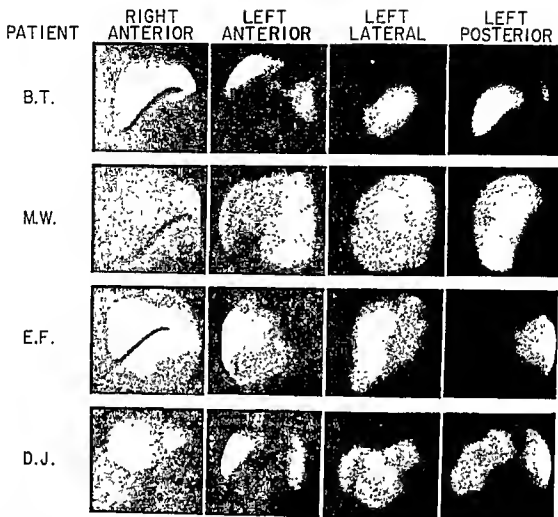

Fig. 45.2 Illustrative <sup>99m</sup>Tc sulfur colloid liver and spleen scans.

*Patient B.T.* had no disease involving the liver or spleen. Note the size and position of the normal liver and spleen in the four panels. The diagonal shadow in panel one is produced by a lead marker placed along the costal margin.

*Patient M.W.* had acute myelomonoblastic leukemia and *E. coli* septicemia at the time of the scan. Note the large liver and spleen in the first two panels and the filling defects in the spleen, more apparent on the left lateral and left posterior views. Splenectomy revealed several splenic abscesses containing *E. coli*.

*Patient E.F.* Polycythemia vera. The spleen was palpable, but numerous Howell-Jolly bodies were present in the blood smear. The liver was large (panel one). The left lobe extended into the left upper quadrant (panel two) and was visible in the anterior portion of the left lateral view. However, the spleen was not visualized. It is presumed that thrombosis of the splenic artery produced functional asplenia.

*Patient D.J.* Liver and spleen scan in a patient who suffered abdominal injuries in an accident. The liver appears intact but several defects are visible in the upper and lower poles of the left lateral and left posterior views. These findings were confirmed by arteriography and several hematomas were found at surgery.

(Prepared with the assistance of Dr. Harold DeBlanc, Division of Nuclear Medicine, University of Utah College of Medicine.)

(Chapter 27) provides useful information.<sup>221,223</sup>

The *total body to venous blood hematocrit ratio* (TB/VH) has been used to assess the degree of *red cell pooling* in enlarged spleens, and was discussed on page 1418.

*Splenic mixing curves* have also proved useful in assessing red cell pooling. These are obtained by continuous counting over the spleen during the first few minutes to an hour after injection of <sup>51</sup>Cr-labeled red cells. If the counts are plotted as the logarithm of the

equilibrium value ( $A_x$ ) minus the value at any time  $t$ , ( $A_t$ ), evaluation of the data is simplified (Figs. 45-3 and 45-4). In normal man the mixing curve consists of a single exponential (Fig. 8-3, page 358), which reaches equilibrium within 1.5 minutes ( $0.91 \pm 0.19$  minute).<sup>228</sup> This curve differs little from that obtained over the heart and reflects the rapid mixing of labeled cells in the normally small (20 to 30 ml) splenic red cell pool.<sup>213,224</sup>

A single-component curve but with a longer than normal  $t_{1/2}$  may be obtained in some patients with splenomegaly (Fig. 45-3).<sup>213</sup> This occurs in congestive splenomegaly and reflects slower than normal mixing in a large pool that is located mainly in the splenic sinusoids.<sup>224</sup> Single-component mixing curves are not associated with splenic hemolysis.<sup>213</sup>

#### Two-component splenic mixing curves

(Fig. 45-4) are obtained if abnormal cells (eg, from patients with hereditary spherocytosis) are transfused into a normal recipient<sup>213</sup>; they also are found in some patients with splenomegaly even after transfusion with normal cells.<sup>213</sup> Two-component mixing curves are the usual kind obtained in patients with hereditary spherocytosis, autoimmune hemolytic anemia, and in some with lymphoma or other forms of splenomegaly.<sup>224</sup> The faster component (line A in Fig. 45-4) reflects slow mixing in the expanded splenic sinusoidal pool, while the slower component (line B in Fig. 45-4) reflects cell trapping (pooling) in the red pulp.<sup>224</sup> Two-component mixing curves may or may not be associated with splenic hemolysis,<sup>213</sup> but some increase in red cell destruction occurs in most enlarged spleens.<sup>223</sup>

When measurements of radioactivity in the

Ordinate (log scale) =  $A_x - A_t$ ; abscissa = time in minutes. Interrupted line = rapid exponential obtained by plotting differences between points on curve B and the values on extrapolation to zero time (From Harris, McAllister, and Prankard,<sup>213</sup> courtesy of the authors and the British Journal of Haematology)

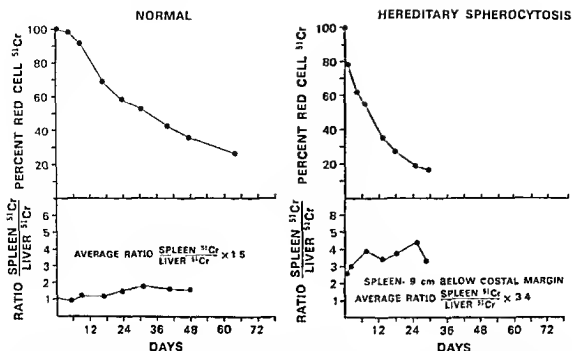

Fig 45-5 Red cell survival and spleen-to-liver ratio curves obtained after the infusion of washed autologous erythrocytes labeled with  $^{51}\text{Cr}$ . Note the shortened red cell survival and increased spleen-to-liver ratio in the patient with hereditary spherocytosis as compared to the normal subject (From Schlosser, Korst, Clatanoff and Schilling,<sup>227</sup> courtesy of the authors and the Journal of Clinical Investigation)

blood and over various organs (*in vivo*  $^{51}\text{Cr}$  localization) are made at intervals extending over a few days to several weeks, still more useful data are obtained.<sup>215,227</sup> Curves depicting the relative accumulation of label in the spleen and liver as compared with the precordium<sup>215</sup> or the spleen-to-liver count ratios<sup>227</sup> may provide evidence of predominant accumulation in one or the other organ (Fig 45-5). Although different indices and modes of data presentation have been used<sup>212,215,217,227</sup> there is general agreement that benefit from splenectomy can be predicted if there is shortening of the red cell  $t_{1/2}$  to less than 15 days and associated progressive accumulation of radioactivity over the spleen. In this regard, a high spleen-to-liver ratio (greater than 2.3) at  $t_{1/2}$  appears to be one of the most useful prognostic indicators.<sup>205,212</sup> Nevertheless, occasional patients with lesser degrees of splenic sequestration have shown an excellent response to splenectomy.<sup>205</sup> This subject has been discussed in Chapter 27 (page 915).

### $^{51}\text{Cr}$ -Labeled Platelets

Similar studies of recovery in the blood after infusion of  $^{51}\text{Cr}$ -labeled platelets and the accumulation of these platelets in the spleen have been utilized to evaluate patients with splenomegaly.<sup>156</sup> This subject has been discussed in Chapter 34. Platelet labeling is less useful in predicting the outcome of splenectomy than are red cell studies.<sup>217</sup>

### Splenic Puncture

American hematologists were slow in adopting biopsy procedures. This was true for bone marrow examination and is still true for splenic and lymph node punctures. Splenic puncture was employed as a means of obtaining material for bacterial culture by Widal and his school at the turn of the century and has been used as an aid in the study of splenomegalies in Europe and in Asia since that time.<sup>238</sup> Lymph node examinations have also been practiced by Europeans for a number of years.<sup>231,233</sup>

Moeschlin<sup>238</sup> recommends that splenic puncture be carried out only when there is distinct splenic enlargement and that it be performed with strictest aseptic technique. The procedure is contraindicated in patients with hemorrhagic manifestations, in those with painful splenomegaly (infarct, etc.) or enlargement due to acute sepsis, and in those who are lethargic or cannot cooperate.

#### *Technique*<sup>238</sup>

The spleen should be carefully outlined. If it is not palpably enlarged, it must be outlined by means of percussion. The patient should also be examined fluoroscopically. By giving a carbonated beverage or 10 g of bicarbonate in a little water followed by a small amount of lemon juice, a bubble of gas is produced in the stomach; the fluoroscope will then show the spleen lying between the gastric gas bubble and the diaphragm.

The puncture is performed in the ninth or tenth intercostal space in the midaxillary line during complete inspiration (Fig. 45-6). Complete inspiration is strongly recommended because a reflex inspiratory descent of the diaphragm is sometimes produced as the needle enters the abdominal cavity and, if the puncture is being done during expiration, there is risk of lacerating the spleen. Puncture of adjacent organs is avoided by using the site recommended. Puncture through the abdominal wall is not desirable as this, even under the best of circumstances, runs the risk of puncture of viscera or displacement of the needle by contraction of the abdominal muscles.

The patient lies flat on his back without pillows under his head. The splenic area is outlined and the lowest limit of pulmonary resonance during full inspiration is determined by light percussion. A site 5 cm below this level is marked. This is where the needle

Fig. 45-6 Splenic puncture. The preferred site of puncture is indicated (From Ferris and Hargraves,<sup>236</sup> courtesy of the authors and Archives of Surgery)

will be inserted. The skin is then painted with an appropriate antiseptic and draped with a sterile eyecloth.

For anesthesia, 4 ml of 2% procaine solution in a 5-ml record syringe, to which is attached a fine needle, 10 cm in length, are used. A cutaneous wheal is produced and then the underlying tissues are infiltrated perpendicularly to the skin surface to a depth of 1 to 2 cm. The patient is asked to breathe rapidly but superficially while the needle is slowly pushed more and more deeply, 1 mm at a time, until slight pain is produced. The development of pain indicates that the peritoneum has been penetrated. The needle is finally pushed 1 to 2 mm further until a scratching sensation is felt as it rubs against the spleen. The depth from the skin to this point is marked on the needle.

For splenic puncture a needle 12 to 15 cm long and 1.2 to 2.0 mm in diameter is recommended. There should be a ground-in stylet and the bevel must not be steep but it should be extremely sharp. A movable guard should be attached to the needle. A 20-ml record syringe is preferred to a smaller one since this permits stronger suction. The needle and syringe must be dry.<sup>236</sup>

On the splenic puncture needle, a distance is marked by setting the guard in a position that is equal to the depth marked on the anesthesia needle plus 2 cm. The additional 2 cm make it possible to penetrate the spleen to a depth of 2 cm and no more. This prevents too deep penetration of the spleen and avoids damage to the larger vessels of that organ. The larger vessels enter at the hilum and end in a fine meshwork at the subcapsular region.

In performing the puncture, the needle is pushed through the spot marked on the skin, the stylet is then removed and the syringe is attached. The patient is told to take a deep breath, close his mouth, and pinch his nose. The needle is then pushed in rapidly to the hilt of the guard. Aspiration is carried out quickly but strongly one or two times. The needle is then withdrawn, but before doing this, negative pressure is gradually released by permitting the plunger to come back

slowly. If this is not done, the negative pressure will bring blood or the anesthetic agent into the syringe and ruin the preparations.

It is important that the patient hold his breath throughout the whole procedure. Before performing the puncture, it is necessary to have the patient practice his role in the steps required. Following the procedure, the patient must remain in bed, lying flat on his back for one hour. At the end of this time he may be given a meal but is asked to remain in bed for another six hours.

Moeschlin has successfully performed many hundred splenic punctures by this technique, without accident. Others<sup>239,242</sup> have used, without trouble, a 20-gauge needle to aspirate, even intercostally, in the area of maximal dullness when the spleen has not been palpably enlarged. With such a needle it was not found necessary to employ a preliminary local anesthetic.

Biopsy with the Vim-Silverman needle is more dangerous and several deaths have occurred following the procedure.<sup>242</sup> Sections obtained with such a needle are especially useful in disorders such as amyloidosis or sarcoidosis in which architecture is more important than individual cell structure.

### *Indications and Interpretation*

The material obtained by splenic puncture usually consists of 1 to 3 drops of rather bloody fluid and a few fragments of tissue. On microscopic examination, 60 to 90% of the cells are found to be lymphocytes. The remainder include granulocytes and reticuloendothelial cells. The latter are mainly derived from the sinuses. Moeschlin's "pulp cells" (Fig. 45-7) have not been observed in tissue obtained from gland or marrow punctures. Other important elements include typical plasmacytoid reticulum cells, identical with those of the marrow, and large lymphatic plasma cells of the same type as those obtained in gland punctures.

Although differential counts (splenograms) can be carried out, an exact splenogram is not usually necessary. Careful examination of films will give a sufficiently accurate idea of

Fig. 45-7. Cells obtained by splenic puncture (Courtesy of Dr. S. Moeschlin) A, Splenic pulp cells, B Dorothy Reed cells in Hodgkin's disease, C, Gaucher cells, D, spleen macrophage with vacuolated cytoplasm, E, Niemann-Pick cell, F, multinucleated epithelioid cell in tuberculosis, G, megaloblasts, pernicious anemia H, hypernephroma cells, from tumor mistaken for spleen

the distribution of the cells and will reveal the presence of abnormal ones.

Splenic puncture<sup>211</sup> is useful in the diagnosis of disorders due to parasites, such as leishmaniasis and malaria; it may serve to differentiate one of the fat-storage disorders from atypical leukemia or splenic neutropenia, and it may be helpful in distinguishing leukemoid reactions from true leukemia.<sup>233,241,242</sup> Splenic puncture also makes possible the demonstration of Dorothy Reed cells in the spleen in patients with abdominal Hodgkin's disease and of epithelioid cells in patients with tuberculosis and in those with brucellosis<sup>219</sup> (Fig. 45-7). In other conditions, the procedure has less importance. In the presence of cirrhosis of the liver and of splenoportal thrombosis, the splenogram is practically normal, even though the spleen may be greatly enlarged. In these conditions the puncture specimen is likely to be unusually bloody. In hemolytic anemia a fairly normal picture has been observed although, as the result of increased blood destruction, hemosiderin-containing macrophages may be quite numerous and some erythroblasts may be observed during periods of exacerbation. Moeschlin did not find signs of phagocytosis of red corpuscles. In patients with pernicious anemia, megaloblasts are plentiful in the spleen.

Hemopoietic foci in the spleen have been described in association with inflammatory splenomegalies.<sup>238</sup> In acute inflammatory reactions, lymphocytes are reduced in number while neutrophils, including stab cells and myelocytes, are increased as are also the pulp cells and macrophages. Only an occasional erythroblast is seen. In chronic inflammatory splenomegalies, in addition to these changes, monocytes, plasmacytoid reticulum cells, and sometimes erythroblasts are increased in number. Cells from these foci may enter the blood in sufficient numbers to arouse a suspicion of early chronic myelocytic leukemia when splenomegaly and leukocytosis are present. In patients with leukemia, however, young myeloid cells form 20 to 60% of the cells whereas in those with chronic inflammatory splenomegaly they do not rise above

1 to 5%. In patients with myelofibrosis with myeloid metaplasia, the persistence of large numbers of lymphocytes (50 to 60%) distinguishes the condition from myelocytic leukemia.<sup>235</sup>

Lymphocytic leukemias are characterized by an almost purely lymphocytic picture (92 to 99%). The cells often vary greatly in size and lymphoblasts in mitosis may be prominent. Normally, mitoses in lymphocytes are rare, their mitotic index having been found to be 50 times less than that of granulocytes. In patients with lymphoid leukemia, the mitoses may be increased 15 or 30 times the normal, although this is not found in all these subjects.

In infectious mononucleosis, at the height of the disease a considerable excess of reticuloendothelial cells, some in mitosis, with transitions between them and the typical infectious mononucleosis cells has been described. In infectious hepatitis, many of the immature precursors of the lymphatic plasma cells that are found in the blood have been observed. Even though splenic aspiration may be diagnostic in from 15 to 33% of patients with splenomegaly<sup>211,212</sup> it has not become a popular procedure in many parts of the world. This may be because it only provides confirmatory information in about one third of the patients studied, is nondiagnostic in an additional one third, and may be misleading or confusing in 10 to 15%.<sup>211,242</sup>

## Indications for Splenectomy

Even though our understanding of splenic function is incomplete, clinical experience affords a good foundation upon which a decision for or against splenectomy in a given patient can be made. Such experience can also be fitted reasonably well with what is known concerning functions of the spleen, as discussed in Chapter 8. Thus, in general, splenectomy has its greatest value when the spleen appears to be exerting a destructive effect on blood cells and is usually unnecessary and unwise when it is serving a con-

structive role, such as antibody production or hematopoiesis.

Vague references to removal of the spleen have been found in ancient Greek and Roman literature extant before the birth of Christ.<sup>249</sup> However, splenectomy in man was apparently first clearly recorded in 1549 and experimental splenectomy in dogs was performed in 1680. Therapeutic splenectomies were recorded in 1826, 1855, and 1865, but the patients all died.<sup>247</sup> Nevertheless, by the late 1800's, series of splenectomies were being reported, chiefly for treatment of cysts, abscesses, injuries, and wounds and for removal of massively enlarged spleens. In one such series reported in 1898, 62% of the patients recovered.<sup>247</sup> As a result of this relative success, splenectomy then was tried in a variety of hematologic diseases with variable results. By 1930 in two series, one of 500 and the other of 118 patients, operative mortality when splenectomy was performed because of thrombocytopenic purpura or congenital hemolytic jaundice had decreased to less than 5%.<sup>254,256,258</sup> However, the results of splenectomy for cirrhosis, sepsis, leukemia, pernicious anemia, and aplastic anemia were less good and operative mortality was higher.

Indications for splenectomy have been discussed in relation to specific disorders in various chapters in this book. There now is general agreement that splenectomy is: (1) regularly beneficial in hereditary spherocytosis (Chapter 21); (2) often useful in idiopathic thrombocytopenic purpura (Chapter 34); (3) beneficial in many patients with acquired hemolytic disease (about 50%) (Chapter 27); and (4) may be beneficial in carefully selected patients with congestive splenomegaly with associated cytopenia.<sup>246,249,260</sup> To these indications some have added (5) Hodgkin's disease, and perhaps some cases of non-Hodgkin's lymphoma for the purpose of staging prior to initiation of therapy (Chapters 50 and 51). Splenectomy in patients with other conditions is more controversial but is indicated under special circumstances. Thus, indications for splenectomy in thalassemia (Chapter 26), the hemoglobinopathies (Chapters 24 and 25), nonspherocytic hemo-

lytic anemias (Chapters 20, 21, and 22), aplastic anemia and pancytopenia (Chapter 56), chronic myelocytic leukemia (Chapter 48), myelofibrosis (Chapter 57), polycythemia vera (Chapter 30), and Gaucher's disease (Chapter 42) are discussed in the appropriate chapters. As stated earlier in this chapter (page 1410), in certain patients with splenomegaly associated with neutropenia or pancytopenia of obscure cause, splenectomy has been claimed to be helpful.<sup>170,250,255</sup>

The necessity for splenectomy in patients having traumatic splenic rupture is obvious. In several centers, 25% of all spleens removed were taken out because of iatrogenic trauma incidental to other abdominal operations.<sup>259</sup> Removal of the spleen because of large cysts or tumors, whether primary or secondary, is relatively unusual.<sup>253</sup> When the cause of splenomegaly has not been clear, and careful evaluation has been inconclusive, *diagnostic laparotomy and splenectomy* revealed lymphoma in 31%, congestive splenomegaly in 25%, and inflammatory disease in 19% of a series of 52 patients reported by Hermann and associates.<sup>251</sup> Similar findings have been reported by others.<sup>245</sup>

### SECTION 3: *Neoplastic Diseases of the Hematopoietic System*

The leukemias and lymphomas, as well as the myelomas and other immunoglobulin-secreting tumors, are considered in this section. The clinical patterns and treatment of each major disease or group of diseases will be reviewed in separate chapters (Chapters 47-53); their classification and possible etiologic basis and their pathogenesis will be considered in Chapter 46. These diseases have many complications in common, but certain complications are more specifically related to certain diseases than to others. The complications of the individual diseases will be described in the chapters dealing with each specific disease; the nature and treatment of the various complications in general will be considered in a special chapter (Chapter 54). Specific methods of treatment for each disease are given in the respective chapters. A detailed discussion of the nature and use of currently available drugs is presented in a separate chapter (Chapter 55).

The cause of neoplastic diseases of the hematopoietic system is unknown. All are characterized by abnormalities in the growth of hematopoietic cells. In certain instances the diseases are curable, but usually they are not, although therapy will ameliorate symptoms and in some patients it will prolong life.

The diagnosis of the leukemias, lymphomas, myelomas, and related diseases is established by demonstrating an increased, and often continually increasing, number of specific hematopoietic cells in the absence of a demonstrable, appropriate stimulus. Cellular excess may be localized to a single lymph node, as in some patients with Hodgkin's disease, or may be quite widespread and involve bone marrow, blood, and many lymph nodes as well as other organs, as occurs in most patients with leukemia. Certain characteristic signs, symptoms, and laboratory findings are anticipated in each disease and these serve as corroborative diagnostic evidence. In certain diseases it is clear that the excessive number of cells is the result of excessive cell proliferation, while, in others, increased life span of the cells may be a primary factor in the cellular accumulation.

## **Classification and Its Historical Development**

The disease classification presented in Table 46-1 is derived from the fact that the major disease categories differ with respect

to morphologic and clinical manifestations, and often in their response to therapy. Few authorities would disagree concerning the recognition of chronic myelocytic leukemia (CML), acute myeloblastic leukemia (AML), chronic lymphocytic leukemia (CLL), acute lymphoblastic leukemia (ALL), Hodgkin's disease (HD), the non-Hodgkin's lymphomas (NHL), multiple myeloma (MM), and macroglobulinemia as distinct entities. Subdivisions of these categories have been proposed, as discussed below and as shown in Table 46-1.

Classification of these diseases has developed out of their gradual historical recognition and the differences observed between them. Thus, in 1666, Malpighi described a fatal disease in which the lymphoid tissue and the spleen appeared "like a cluster of grapes."<sup>7</sup> In 1832, Hodgkin<sup>13</sup> described the gross anatomy of seven patients with fatal illnesses associated with lymph node enlargement; the disease in three of these patients would now be assigned the eponym to which Hodgkin's name is given.<sup>5</sup> It was Wilks, however, who, in 1856, provided a lucid description of HD as it is now recognized.<sup>7</sup> The studies of Kundrat<sup>14</sup> (1893), Longcope<sup>16</sup> (1907), and others led to the clear pathologic separation of HD from NHL. Roulet<sup>24</sup> distinguished reticulum cell sarcoma from other

**Table 46-1. Classification of the Neoplastic Diseases of the Hematopoietic System**

- I **Leukemias**
  - A Granulocytic leukemias
    - 1 Chronic myelocytic leukemia (myelogenous granulocytic)
      - a Atypical chronic myelocytic leukemia
      - b Chronic eosinophilic leukemia
      - c Chronic basophilic leukemia
      - d Chronic monocytic leukemia
    - 2 Acute myeloblastic leukemia (myelocytic, granulocytic, myelogenous)
      - a Acute myelomonoblastic leukemia
      - b Acute monocytic leukemia
      - c Acute promyelocytic leukemia
      - d Acute erythroblastic leukemia
      - e Acute eosinophilic leukemia
      - f Acute basophilic leukemia
      - g Chloroma
  - B Lymphocytic leukemias (lymphoid lymphogenous)
    - 1 Chronic lymphocytic leukemia
      - a Chronic lymphosarcoma cell leukemia
      - b Sezary syndrome
    - 2 Acute lymphoblastic leukemia (stem cell)

lymphosarcomas; giant follicle lymphoma was first described by Ghon and Roman<sup>10</sup> and was recognized as clinically distinctive by Brill et al<sup>3</sup> as well as by Symmers.<sup>27</sup> The giant polyploid macrophage which most consider the *sine qua non* of HD was first described by Langhans,<sup>15</sup> again by Greenfield,<sup>12</sup> and later by Sternberg, who mistakenly attributed it to tuberculosis.<sup>25</sup> Reed<sup>21</sup> was the first to emphasize its unique relationship to HD and the eponym "Reed-Sternberg" cell is commonly applied.

Leukemia was distinguished as a separate clinical entity by Craigie, Bennett,<sup>1</sup> and Virchow<sup>29</sup> in 1845. Virchow recognized that the cells involved did not represent suppuration of the blood and proposed the name "leukemia" (white blood). He later distinguished two forms of leukemia, one in which splenomegaly predominates and another in which lymphadenopathy is most prominent. Leukemia with an acute course was first reported by Friedreich<sup>8</sup> (1857). Ebstein<sup>6</sup> (1899) described the outstanding symptoms of acute leukemia. It was not until Ehrlich's blood-staining methods came into use that specific types of leukocytes were related to the different clinical syndromes. With Naegeli's recognition of the myeloblast in 1900<sup>20</sup> and with Reschad and Schilling-Torgau's description, in 1913,<sup>23</sup> of what these authors thought was monocytic leukemia, the major divisions of the leukemias, as we now categorize them, were reasonably complete.

The term "multiple myeloma" was suggested in 1873 as the result of Rustizky's pathologic studies of a disease characterized by softening and fractures of bones and the presence of a peculiar protein in the urine.<sup>25</sup> The latter had been described as early as 1845 by McIntyre, Dalrymple, Watson, and Bence Jones.<sup>9</sup> Multiple myeloma was further characterized by the studies of Kahler (1889) and Bozzolo (1897). Wright (1900) drew attention to the similarity between plasma cells in bone marrow and the cells making up the tumors of multiple myeloma.<sup>9,25</sup> The association of multiple myeloma with hyperproteinemia was first noted by Perlzweig (1928) and elaborated by Magnus-Levy (1938).<sup>18</sup>

The presence of a cold-precipitable plasma protein was described by Wintrobe and Buell (1933)<sup>30</sup> Introduction of serum protein electrophoresis by Tiselius led, in 1939, to Longsworth and coworkers' description of the serum protein "spike" typical of multiple myeloma.<sup>17</sup> Since then, continuing refinement in methods of examination of proteins in serum and urine has permitted the recognition of a number of diseases characterized by overproduction of immunoglobulins or fractions thereof (Chapters 52 and 53).

Thus, by the first part of the 20th century the framework for the major subdivisions of neoplastic diseases of hematopoietic tissue had been developed. Discussions concerning further subdivisions of major categories continue to the present time and probably will persist until the etiology and pathogenesis of these diseases are better understood.

Leukemia is unquestionably divisible into granulocytic and lymphocytic varieties. These in turn may be separated into acute and chronic forms. Since, as the result of improved therapy (Chapter 47), some patients with acute lymphoblastic leukemia may live longer than patients with chronic myelocytic leukemia, the designations "acute" and "chronic" are no longer applicable to life span.<sup>2</sup> Nevertheless, they are still retained since they are appropriate with respect to the rapidity of development of symptoms, signs, and complications in these forms of leukemia. The use of the term "subacute" is discussed in Chapter 47.

The lymphomas are conveniently separated into two broad categories, HD and NHL. Hodgkin's disease has been further subdivided according to histologic patterns because these are of prognostic significance (Chapter 50). Subdivisions of NHL are discussed in Chapter 51. Mycosis fungoides is difficult to define as a distinct pathologic entity (Chapter 51).<sup>4</sup> The distinctive geographic distribution and exquisite sensitivity to therapy of Burkitt's (African) lymphoma justify its consideration as a separate entity (Chapter 51). Whether histiocytic medullary reticulosis and the ill-defined group of diseases often regarded as reticuloendothelioses

should be considered as lymphomas is debatable. However, since many authorities consider them to be neoplastic diseases of hematopoietic tissue, they are discussed in Chapter 51.

The immunoglobulin-secreting tumors differ somewhat from one another in their clinical and laboratory manifestations as well as with respect to the type of protein produced by the immunocyte clone (Chapters 52 and 53).

Other diseases discussed in this volume that are considered neoplastic in nature by some investigators are polycythemia vera (Chapter 30) and idiopathic myelofibrosis with myeloid metaplasia (IMF), as well as certain related diseases (Chapter 57).

## Interrelations of the Diseases

A number of aspects of the neoplastic disorders of the hematopoietic system suggest interrelationships or even "conversion" from one disorder to another.

"Conversion" from one to another disease most commonly is manifested by a change in the pathologic appearance of lymph nodes or by changes in the blood (leukemic conversion). In the latter situation, the blood is invaded by lymphoma cells or a leukemia-like picture develops in patients with polycythemia vera or myelofibrosis.

As lymphoma progresses, the architecture may change. The frequency with which a follicular pattern leading to classification as nodular lymphoma changes to a diffuse pattern has led many pathologists to disregard this as a distinct entity. In another form of conversion, lymph nodes from patients with HD in which the initial pattern is one of lymphocyte predominance may become progressively depleted of lymphocytes if cure has not been achieved (Chapter 50).

A leukemic pattern morphologically and clinically similar to that of CLL or ALL may develop in any type of non-Hodgkin's lymphoma (Chapter 51). Leukemic conversion is more common in children than in adults and

in children the leukemia is more likely to be lymphoblastic than lymphocytic.<sup>45</sup>

Blastic transformation of CML is the cause of death in most patients with CML (Chapter 48). Patients with CML may also develop marrow fibrosis similar to that seen in IMF (Chapter 48). Patients with polycythemia vera (PV) (Chapter 30) and, more often, those with IMF (Chapter 57) may develop a picture resembling CML or they may die with a blastic transformation. Rarely, polycythemia may develop in patients presenting with a CML- or IMF-like disease.<sup>42</sup> Sequential conversion from CML to PV, to IMF, to terminal AML has been noted.<sup>43</sup> The possible development of histiocytic neoplasms in CML<sup>31,41</sup> is discussed in Chapter 48.

The individuality of stem cells for the lymphocytic and myeloid cell lines (Chapter 2) is borne out by the rarity with which a myeloid neoplasm is converted to a lymphoid one, or vice versa. Development of AML or its variants has been observed in at least 14 patients with HD<sup>33</sup> and in 31 with myeloma or related diseases.<sup>44</sup> However, such patients usually had been treated by irradiation in large doses or with radiomimetic drugs so that such conversion may represent induction of leukemia by known leukemogens (page 1455) rather than the natural history of the disease. An excess of the occurrence of second malignant conditions has been noted in HD patients treated by either chemotherapy or radiation therapy and particularly in those treated by both modalities.<sup>32</sup>

The significance of reports such as that of ALL terminating in a picture resembling histiocytic medullary reticulosis<sup>35,38</sup> remains to be clarified.

The existence of changes such as those described above and the observation that some cases are difficult to categorize led Dameshek to suggest that these conditions be termed "myeloproliferative" or "lymphoproliferative" disorders<sup>38,39</sup> according to whether or not they seemed to originate from myeloid or lymphoid tissue, respectively. This is an interesting, broad descriptive concept, but, unfortunately, these terms have been misused by some physicians to imply a diagnosis.

## Incidence

Death rates from all types of cancer in the United States' population, 1950 through 1967, have been compiled.<sup>34</sup> Leukemia, lymphoma, and myeloma are responsible for approximately 10% of all cancer deaths (Table 46-2). The incidence of leukemia and lymphoma reported from Denmark, 1943 to 1957, is remarkably similar<sup>36</sup> to that in the United States. Incidence calculated by deaths, however, fails to include any cured patients. Consequently, the incidence of HD must be somewhat in excess of the figures given in Table 46-2.

At the present time, acute and chronic leukemia appear to be equally frequent and CLL is slightly more common than CML (Table 46-2) (Fig. 46-1). Leukemia and lymphoma are approximately equally frequent. Reporting of cell types varies so much from institution to institution that, except for noting that less than half of all lymphomas are HD, little can be said for their exact frequency.

### Changing Incidence of Disease

Steadily increasing mortality rates for leukemia in general were reported for the United States and other countries for many years.<sup>40</sup> This is evident between 1950 and 1958, as shown in Table 46-2. The rise has apparently slowed or ceased in the white population of the United States. Evidence for stable rates of mortality for leukemia among children in Connecticut between 1945 and 1959 and for all types of leukemia in Cornwall from 1948 through 1959 confirms the stability of present leukemia rates.<sup>40</sup> Whether the reported rising mortality of years past was real or artifactual is difficult to determine. The influence on mortality statistics of improved medical care, increasing use of laboratory diagnosis, improved disease certification, some increase in life span, and the fairly high frequency of leukemia in the elderly must be considered in evaluating the data. Features suggesting that leukemia may have been a less common disease in years past are the magnitude of the

## AGE AND SEX OF 565 PATIENTS WITH LEUKEMIA

Fig 46-1. Types and age and sex distribution in 565 patients with leukemia examined in the authors' clinic (From Boggs et al,<sup>33a</sup> courtesy of the authors and Williams & Wilkins Company)

rise, a seemingly disproportionate increase in certain types of leukemia, and some evidence for changing sex differences.<sup>40</sup> The validity of the statistics is further supported by the observation that the incidence of childhood leukemia increased significantly in Israel between 1950 and 1960, while the lymphoma rate was constant.<sup>46</sup>

There is a suggestion of rising rates of NHL, but rates for HD appear quite stable (Table 46-2). The reported death rate from multiple myeloma has more than doubled between 1950 and 1967, a change that must reflect, at least in part, the widespread current use of protein electrophoresis as a diagnostic test.

#### Age Incidence

Age specific death rates for all of these diseases except acute lymphoblastic leukemia

increase dramatically and fairly steadily after the fifth decade of life has been reached.<sup>34</sup> The age specific rate for all forms of leukemia is shown in Figure 46-2. In the white male population, the rate decreases from 4.6 to 2.1/100,000 between the first and third decades. This early peak reflects the peak of ALL seen at age three to four years (Fig. 46-1). ALL becomes quite uncommon by the fourth decade (Chapter 47). Conversely, CLL is virtually unknown in persons younger than 30 years. AML and CML can occur in persons of any age, but become progressively more frequent as the population reaches middle age.

Hodgkin's disease has a somewhat peculiar age distribution in that there is a steady rise in incidence during the first three decades of life, the rise then slowing for two decades and again increasing to a peak in the seventh decade (Fig. 46-3). The early peak is more

Fig 46.2. Age specific death rate from leukemia in the United States population. (From Burbark,<sup>34</sup> courtesy of the author and National Cancer Institute)

Fig. 46-3. Age specific death rate from Hodgkin's disease in the United States population (From Burbank,<sup>14</sup> courtesy of the author and National Cancer Institute)

pronounced in women than in men. This distribution has led to the hypothesis that the two peaks represent different types of disease<sup>37</sup>; the nodular sclerosis type (Chapter 50) may account for the early peak.<sup>45</sup>

NHL is observed in persons of any age, although the follicular forms are rarely seen in children.<sup>45</sup> The incidence is virtually the same throughout childhood and adolescence, but rises progressively thereafter.<sup>34</sup> Multiple myeloma rarely is found in persons younger than 30 years and reaches a peak incidence in those in their seventh decade, after which the rate declines.<sup>34</sup>

Since the size of the population at risk changes with age, age specific rates are not reflected in age frequency at diagnosis. Thus, most patients with CML or AML are found to be in their middle years (Fig. 46-1) if calculations are made according to age specific rate and population size.

### Sex Ratios

All of the neoplastic diseases of the hematopoietic system are more common in males than in females (Table 46-2) (Figs. 46-1, 2, and 3). Male-to-female ratios range from approximately 3:2 for acute leukemia, to 2:1 for CLL. The least degree of male-to-female preponderance is among children with ALL in whom the ratio is approximately 5:4.<sup>34</sup> In most of the diseases under consideration the rate of increase in later decades of life is faster for males than for females, accentuating sex differences as age increases.<sup>34</sup>

### Pathogenesis

All of the neoplastic diseases of the hematopoietic system represent disordered cell growth. In this section, data relating to the following questions are reviewed: Are these tumors unicentric (clonal) or multicentric in origin? Are the cells abnormal by functional or biochemical definition? What are the cellular growth rates and life spans (kinetic data)? Are control mechanisms for cellular growth intact or aberrant?

The primary cell involved in the malignant process in LSA, CLL, and ALL is presumed

to be the morphologically identifiable lymphocyte or lymphoblast. Since the plasma cell may not be a dividing cell (Chapter 7) a lymphoid precursor may be responsible in MM. Of the mixed cellular accumulation observed in HD, the Reed-Sternberg cell and its presumed relative, the histiocyte, are considered to be the "malignant" cells. In CML and AML there is evidence to suggest that the defect lies not in the myeloblast but in a pluripotent precursor (see Chapter 2 for normal stem cell systems). The Ph<sup>1</sup> chromosome defect described in the majority of patients with CML (page 1441) is found in neutrophil, eosinophil, erythrocyte, and platelet precursors. It seems reasonable to suggest that CML represents a stem cell defect in which increased and probably uncontrolled cell flow into neutrophil, eosinophil, monocyte, basophil, and platelet compartments accounts for the increase of these cells in the blood, while decreased flow into the red cell compartment results in anemia. In AML there is a flow into the myeloblast compartment, but it is abortive in that maturation is incomplete and there is decreased flow into the platelet and red cell compartments.

### Evidence for Clonal Disease

The pattern of spread of HD suggests that it may be clonal in nature and strong evidence for clonal origin can be marshalled for MM and CML and, to some degree, for the other neoplastic diseases of the hematopoietic system.

The homogeneous protein produced in MM contains either kappa or lambda light chains (Chapter 52) rather than the mixture of the two types found in normal immunoglobulins (Chapter 7). Although alternative hypotheses could explain this observation it is most simply interpreted on the assumption that MM begins in a single cell that produces a single type of light chain, the disease resulting from multiplication of that single cell. When two homogeneous proteins have been present, both have had homogeneous light chains, suggesting the presence of two distinct clones<sup>136</sup> (Chapter 52).

Evidence that CML is clonal is quite

strong and is derived from chromosomal (below) and cellular isozyme studies. Patients heterozygous for the A and B isozymes of 6-phosphogluconate dehydrogenase are found to have approximately equal representation of the A and B isozymes in their normal tissues.<sup>95,96</sup> When such heterozygotes have developed CML, analysis of their myeloid tissue reveals only one isozyme, A or B, while their nonleukemic tissues still contain an approximately equal mixture of A and B.<sup>95,96</sup> Interpreted most simply, these data suggest that CML begins in a single cell in which genetic expression of one isozyme is repressed or deleted.<sup>96</sup>

The clonal origin of AML from a pluripotent stem cell finds support in chromosome studies (page 1443). Additional evidence is found in studies suggesting that there are two separate and distinct red cell populations in patients with DiGuglielmo's syndrome, which differ with respect to content of A<sub>2</sub> hemoglobin, surface antigens, and enzyme content.<sup>130</sup> Again, certain patients with AML have a subpopulation of red cells abnormally susceptible to in vitro lysis.<sup>81</sup> In another study, abnormal DNA synthesis was described.<sup>81</sup> These observations suggest, but do not prove, that a pluripotent stem cell clone is producing abnormal red cells, although normal stem cells persist and produce normal red cells as well.

That CLL may be clonal in origin is suggested by the observation that lymphocyte surface immunoglobulins, often IgM protein,<sup>52</sup> may be homogeneous for kappa or lambda light chains.<sup>64,178</sup> Surface or even unreleased, intracellular homogeneous proteins are often present, even when such proteins are not detectable in serum.<sup>124</sup>

Examination of 33 of 34 patients with Burkitt's lymphoma suggested a clonal origin of the tumor by isozyme criteria and evidence for clonal origin was obtained in 92 out of 95 cases by immunoglobulin markers.<sup>96a</sup>

### Chromosome Abnormalities in Tumor Cells

A wide variety of chromosome abnormalities (Chapter 2) have been described in the

leukemias and lymphomas.<sup>186</sup> These chromosome abnormalities apparently are limited to the tumor cells since normal somatic cells such as skin and buccal mucosa are diploid and manifest no morphologically identifiable defects in individual chromosomes.

### Chronic Myelocytic Leukemia

In 1960, Nowell and Hungerford<sup>157</sup> described an abnormally small chromosome in patients with CML, the *Philadelphia (Ph)* chromosome. Subsequent studies demonstrated that 80 to 90% of patients with a "typical" clinical picture of CML have this defect (Chapter 48).

The Ph<sup>1</sup> chromosome<sup>186</sup> is a G-group chromosome, number 22,<sup>163</sup> which has lost a portion of its long arms. It is generally believed that the lost portions have been translocated rather than having been lost and there is evidence to suggest that the translocation is to chromosome number 9.<sup>179</sup> The amount of missing DNA, while averaging 30 to 50%,<sup>181</sup> seems to vary from patient to patient as judged by morphologic studies. Whether such variation is real or artifactual must await more accurate methods of measuring DNA per chromosome. If such variation does exist, it is conceivable that patients with typical CML, but without a morphologically identifiable Ph<sup>1</sup> chromosome, may in fact lack a very small, morphologically undetectable, portion of the long arms. The Ph<sup>1</sup> chromosome is present in marrow cells, but not in lymphocytes, so direct metaphase smears of marrow or blood rather than blood cultured in phytohemagglutinin should be studied in order to detect its presence.

The Ph<sup>1</sup> chromosome is found not only in neutrophilic granulocytic cells, but also in eosinophils,<sup>132</sup> normoblasts, and probably in megakaryocytes.<sup>212</sup> As noted in Chapter 2, this observation suggests that these cell lines share a common stem cell. The abnormality, when present, is found in virtually 100% of marrow cells in most patients. In occasional ones the Y chromosome also is lost so that the cells are hypodiploid.<sup>167</sup> Other changes may occasionally be present in the absence of blastic transformation.<sup>166,186</sup> That the de-

fect is acquired during the evolution of CML rather than being inherited is borne out by its absence in unaffected members of identical twins.<sup>87,110,111</sup>

These observations suggest that CML is a clonal disease; that is, it begins with a single, abnormal stem cell that has characteristics allowing it to proliferate in preference to normal stem cells. However, residual normal hematopoietic stem cells that do not contain the  $\text{Ph}^1$  defect are demonstrable in some patients with CML.<sup>83</sup> The abnormality does not disappear with therapy in most instances. Reports of its disappearance from the marrow of patients treated until severe pancytopenia was induced<sup>117,200,209</sup> do not allow determination of whether metaphases from myeloid cells or residual lymphocytes were studied. However, one patient has remained in remission for more than a decade with only a persistent, minor  $\text{Ph}^1$  marrow population.<sup>88</sup> Additional evidence for the clonal nature of CML, as judged by chromosome changes, is found in studies of a 69 year old phenotypically normal male who was a sex chromosome mosaic.<sup>101</sup> Barr bodies (Chapter 2) could be found in his neutrophils. Lymphocytes and marrow cells were chromosome mosaics of XY and XXY. However, the  $\text{Ph}^1$  chromosome was seen only in marrow cells, specifically the XY cells, and did not involve the XXY line in the marrow.

Radiation leads to an increased frequency of CML as well as AML (page 1456). Patients developing CML after irradiation exposure have been found to have the  $\text{Ph}^1$  defect.<sup>20</sup> Perhaps of even greater interpretive value with respect to the significance of this defect is its presence in patients exposed to irradiation who had not, at the time of the reports, developed CML.<sup>109,126</sup> If these patients should develop CML, it would strengthen the case that this defect is basic in the pathogenesis of the disease.

In contrast to the usual finding that the  $\text{Ph}^1$  abnormality is limited to myeloid cells, a family has been observed in which this defect was inherited and thus was present in all cells.<sup>217</sup> The presence of CML in two of these family members and unexplained neutrophilia in a third provide support for the

thesis that this defect may cause CML. However, in other families in whom more than one member developed CML, evidence for  $\text{Ph}^1$  abnormality was not found.<sup>58</sup> It must also be considered possible that the  $\text{Ph}^1$  abnormality, rather than being the cause of CML, is produced by the agent or mechanism causing CML.<sup>186</sup> For example, an oncogenic virus might produce a reproducible chromosome defect in any cell that it infects.

The  $\text{Ph}^1$  change has been observed in a few patients with seemingly typical AML, erythroleukemia, myelofibrosis, "essential thrombocythemia," and polycythemia vera.<sup>186</sup> Since CML can evolve into a picture virtually indistinguishable from at least the first four of these diseases (page 1435) it can be argued<sup>214</sup> that the cases represented undetected CML. Nevertheless, in the absence of firm knowledge of the role of the  $\text{Ph}^1$  chromosome in CML, the significance of its presence in patients with these diseases remains uncertain. For one thing, it may not be the identical defect in all these conditions, despite morphologic similarity. Conversely, the same defect might lead to different aberrant cellular expressions in different individuals, a concept compatible with suggestions that all of these diseases are very closely related (page 1434).

#### *Chromosome Changes during the Blast Phase of CML*

A variety of aneuploid and other random defects fairly typical of the defects observed in AML (see below) have been observed during blastic transformation of CML (Chapter 48). However, the most intriguing observation during blast crisis is the frequency with which a second  $\text{Ph}^1$  chromosome has appeared.<sup>80,186</sup> The number of second  $\text{Ph}^1$  chromosomes has decreased with remission and again has risen with return of crisis.<sup>80,205</sup> This suggests, but does not prove, that the blast crisis is the result of a new clone of cells arising within the leukemic population. Since the changes during the blast crisis of CML usually follow prolonged therapy, one may ask whether the changes represent the natural evolution of this disease or are the result of therapy. The infrequency of new abnormali-

ties developing in AML after prolonged therapy<sup>186</sup> suggests natural evolution.

### Acute Leukemias

As in CML, karyotypic changes, when present, appear to be limited to marrow and/or lymphoid cells involved in the acute leukemic process. Karyotypic changes are demonstrable in approximately 50% of patients with acute leukemia (either AML or ALL) (Table 46-3).<sup>101a,128,186,213,214</sup> This number suggests that if these are clonal diseases, the abnormal clones may not be expressed in a morphologically identifiable karyotypic form in all patients. Aneuploidy is the most common finding in acute leukemia and is unusual in other disturbances of the hematopoietic system except in congenital diseases. Its presence in the majority of cells from direct preparations of marrow or blood is strongly suggestive of acute leukemia; a few aneuploid cells, however, in the presence of a predominant diploid line are commonly found in marrow from patients without hematologic disease.<sup>162</sup> Certain refractory anemias have been reported to be associated with aneuploid changes similar to those found in AML.<sup>119,186</sup> Some such patients, especially those with sideroblastic anemia,<sup>132,184</sup> have proved to be "preleukemic," but many have not.<sup>143,184</sup>

The findings in ALL differ somewhat from those in AML (Table 46-3). Aneuploidy is almost always of a hyperdiploid nature in ALL,<sup>101a,213</sup> while hypo- and hyperdiploid cell lines are found with approximately equal frequency in AML. The autosomal group involved in duplication or omission is not the same from one patient to another. However, C and G group chromosomes are involved more often than are F group chromosomes.<sup>101a</sup> One patient with AML was found to have a tetraploid line of cells (92 chromosomes).<sup>210</sup> In addition, abnormal-appearing chromosomes may be observed.<sup>128,170,186</sup> In individual patients the same chromosome abnormality may reappear with relapse, after having disappeared during remission.<sup>186</sup> In others, different lines may appear with relapse.<sup>62,101a</sup> If no chromosomal changes

**Table 46-3. Chromosome Number in Acute Leukemia\***

Modal Number of Chromosomes (% of Patients)	Acute Myeloblastic (113 Patients)	Acute Lymphoblastic (106 Patients)
Hypodiploid	28%	1%
Diploid	50%	51%
No abnormality	(36%)	(41%)
Aneuploid subline	(14%)	(10%)
Hyperdiploid	22%	48%

\*Adapted from Sandberg and Hossfeld.<sup>186</sup>

are present initially in acute leukemia, they rarely develop, even with prolonged therapy.<sup>128,186</sup> Variants of AML, such as the DiGuglielmo syndrome, manifest chromosomal changes indistinguishable from those of AML.<sup>122,129,186</sup>

Unlike CML, in which the Ph<sup>1</sup> chromosome is present in virtually all marrow cells, some cells with normal karyotype are often present in acute leukemia, especially in ALL.<sup>101a</sup> This, plus the disappearance of chromosomal abnormalities during remission, suggests that abnormal and normal cells coexist in acute leukemia. The significance of this, like the significance of the Ph<sup>1</sup> chromosome in CML, depends on whether the defect is responsible for or merely a manifestation of the disease.

In patients with what has been described as "chronic monocytic leukemia" (Chapter 48) there is a high frequency of deletion of the Y chromosome in marrow, but not in other cells. This suggests that the defect is acquired.<sup>123,153</sup>

### Protein-Secreting Tumors

Cultures of marrow as well as PHA-stimulated cultures of blood lymphocytes reveal chromosome abnormalities in the majority of patients with protein-secreting tumors.<sup>186</sup> Cells with abnormalities always coexist with karyotypically normal cells and normal cells usually are in the majority. Since there has been no way to determine the origin of the

karyotypically abnormal cells the suspicion that they are tumor cells has not been confirmed. Although a variety of structural abnormalities as well as various types of aneuploidy have been described, approximately 80% of patients with macroglobulinemia and 30% of those with myeloma have a supernumerary group A size chromosome (Chapter 2). However, the morphologic characteristics of the extra chromosome have varied considerably from patient to patient. These abnormal chromosomes have not been found in fibroblasts<sup>93</sup> nor in a healthy monozygotic twin of an affected patient,<sup>201</sup> thus suggesting that this is an acquired defect.

### Chronic Lymphocytic Leukemia

An inherited abnormal G group chromosome, probably number 21, has been demonstrated in some families in which more than one member had CLL.<sup>100,186</sup> Since a similar abnormality has been found in individuals with no evidence of CLL the association may be fortuitous, rather than causally related.<sup>186</sup> Actually, data on chromosomes from patients with CLL are of questionable value. Their lymphocytes rarely divide in short-term culture, nor do they undergo blastic transformation when cultured with phytohemagglutinin (page 1448). Thus, reliable analyses of chromosome constitution of the lymphocytes involved in the CLL process are not available. The significance of occasional reports of random abnormalities,<sup>186</sup> such as abnormal frequency of aneuploid cells and chromatid breaks in patients in whom most metaphases were normal,<sup>219</sup> as well as the as yet unconfirmed report of a slight reduction in the size of small acrocentric chromosomes in males with this disease,<sup>99</sup> remains to be determined.

### Polycythemia Vera

Most patients with polycythemia vera are karyotypically normal. Of those in whom abnormalities have been reported, most had received extensive therapy, especially with <sup>32</sup>P and/or often their condition was evolving

into one simulating AML.<sup>186</sup> However, the finding of extra C group chromosomes in two untreated patients and a missing Y in another suggests that chromosome changes may sometimes occur in this disease, especially since the frequency of abnormal metaphases was found to decrease with therapy.<sup>133,186</sup>

### Lymphomas

Short-term cultures of lymph node cells from patients with *Hodgkin's disease* have shown a high frequency of hyperdiploid cells, but marrow cultures usually have given normal findings. Reed-Sternberg cells are polyploid under ordinary light microscopy, and whether or not the frequency of aneuploidy merely reflects the frequency of Reed-Sternberg cells remains a question.<sup>186</sup> A small proportion of cells with abnormal karyotypes have been reported in patients with *non-Hodgkin's lymphoma*. Most of these appeared to be randomly distributed and consisted of aneuploidy, or abnormally long arms were present on certain chromosomes.<sup>186,202</sup> Cytogenetically mutant clones have arisen in subcultures of an initially modally normal cell culture of Burkitt's lymphoma, but most direct cultures from patients with this disease have shown no cytogenetic abnormality.<sup>135</sup> Deletion of either the long or short arms of chromosome 17 or 18 in the E group has been reported in a few patients with NHL as well as in patients with Hodgkin's disease.<sup>151,194,202</sup> These chromosomes coexisted with cells of normal karyotype. Additional surveys will be required to determine if this abnormality is more frequent than other changes in these diseases. Hyperdiploid cells in direct marrow culture from patients with NHL have been observed to disappear with remission and to reappear with relapse.<sup>187</sup> Chromosome abnormalities were seen in tumor cells, but not in somatic cells in a patient from a family with a high incidence of lymphoma.<sup>131</sup>

In the disease or group of diseases that are considered under the heading of *myelofibrosis* (Chapter 57), chromosome changes rarely occur until the disease has evolved into a picture resembling that of AML.<sup>186</sup>

## Summary

Studies of chromosomes suggest, but do not prove, that CML, certain acute leukemias, the protein-secreting tumors, and perhaps certain lymphomas are clonal in nature. If this is so, there could be an initiating factor causing the production of the initial abnormal cell, or the chromosome abnormality may occur by chance. If an initiating factor, for instance, a virus, were incorporated into DNA, one might ask whether its persistence is required or is the genetic alteration perpetuated without viral persistence (page 1450). Certainly acquired chromosome abnormalities may disappear. In vitamin B<sub>12</sub> deficiency (Chapter 14), giant chromosomes and chromosomes with breaks are observed in metaphases from direct cultures of marrow and yet these disappear with B<sub>12</sub> therapy.<sup>131</sup>

An increased incidence of chromosome abnormalities, including some "clones," has been reported in healthy A-bomb survivors.<sup>68</sup> Chromosome aberrations are associated with virus-induced leukemia in mice. However, these are not detectable until the disease is fairly well advanced, suggesting that the chromosome changes are epiphenomena rather than essential to the development of leukemia.<sup>173</sup> In this regard it is of some interest that abnormalities similar to those induced by infection with SV 40 virus have been found in lymph node cells from patients with reticulum cell sarcoma.<sup>202</sup>

Abnormality of chromosome 21 or 22 in association with the leukocyte abnormalities of CML, Down's syndrome, familial CLL, and sideroblastic anemia when evolving into AML<sup>198</sup> would suggest that some essential control genes for leukocytes may be present in either or both of these chromosomes. On the other hand, the absence of leukocyte changes in two instances of monosomy of 21-22<sup>253,244</sup> casts doubts on this suggestion.

## Functional and Biochemical Abnormalities of Tumor Cells

Warburg's suggestion that all forms of cancer are characterized by an abnormally

high rate of aerobic glycolysis has not found scientific support.<sup>59</sup> However, Greenstein's hope<sup>59</sup> of finding an enzyme unique to cancer remains a viable hypothesis, at least in regard to RNA-dependent DNA polymerase (page 1454). Presently available data suggest that the cells involved in leukemia, lymphoma, and myeloma often are functionally deficient and biochemically abnormal.<sup>112,174</sup> It is not clear whether this reflects an intrinsic abnormality, a cellular response to an abnormal environment, or simply overgrowth of a normal subpopulation of cells whose characteristics differ from those of the major population. This interpretive dilemma is apparent in studies relating to CLL.

## Lymphocytes

The cell involved in CLL is the small lymphocyte. While subtle differences between its appearance and that of normal small lymphocytes may be noticed by light<sup>206</sup> or electron<sup>192</sup> microscopy, in most cases the cell appears normal. The normal function of the lymphocytic system is antibody production (Chapter 7) and evidence for defects in both humoral and cellular antibody systems is found in patients with CLL. Defective production of humoral antibody in response to antigenic challenge is present to a variable degree in most patients and is often reflected in hypogammaglobulinemia.<sup>153,197</sup> Skin reactions of delayed hypersensitivity are not lost,<sup>197</sup> but introduction of a new antigen may fail to elicit a positive skin response.<sup>67</sup> Blastic conversion in response to phytohemagglutinin (PHA)<sup>50</sup> or to allogeneic lymphocytes<sup>159</sup> is reduced in magnitude and is delayed as compared to that of normal lymphocytes, perhaps reflecting a decrease in surface receptor sites.<sup>156</sup> The response to PHA returns toward normal as blood lymphocyte concentration is reduced by therapy.<sup>50</sup> The chemical characteristics of the cells are similar to those of normal lymphocytes, but they live longer than normal lymphocytes in tissue culture and are abnormally susceptible to killing by adrenal corticosteroids and guinea pig serum.<sup>191</sup> Repair of x-ray- or ultra-violet-induced DNA damage

is enhanced in lymphocytes from patients with CLL as compared to those from normal persons,<sup>117</sup> and their RNA pattern differs.<sup>189</sup> Thus, there is evidence that the population of lymphocytes in patients with CLL differs significantly from normal.

However, it is known that the morphologically similar population of normal small lymphocytes is made up of functionally diverse subpopulations (Chapter 7). In normal individuals, some 25 to 50% of blood lymphocytes have a high density of surface immunoglobulin while the remainder have little or no detectable surface immunoglobulin.<sup>218</sup> The former cells are considered to be "bone marrow" (B) lymphocytes and the latter "thymic" (T), by analogy with similar studies in mice (Chapter 7). The percentage of "B" lymphocytes is markedly increased in many patients with CLL,<sup>52a, 172, 173, 178, 218, 219a</sup> while in some patients the cells are not identifiable as either "T" or "B" cells.<sup>178</sup> The relative decrease in "T" cells in such patients may explain their unresponsiveness to phytohemagglutinin since this response is considered a function of "T" cells. Thus, it cannot be determined if the excessive lymphocytes in this disease represent an abnormal or an expanded but normal population.

Although little is known concerning cellular chemistry in non-Hodgkin's lymphoma, immunologic defects similar to those found in CLL are common.<sup>152</sup> Blood lymphocytes from patients with NHL may fail to undergo blastic transformation with PHA,<sup>63</sup> suggesting that the circulating lymphocytes are involved in the disease. Extracts of tumor tissue from various types of lymphomas revealed excessive IgA, IgG, or IgM in some, but reduced immunoglobulin levels were found in others, suggesting that some might have arisen from "B" cells and others from "T" cells.<sup>207</sup> Consistent with this is the observation that lymphocytes in the circulation of patients with NHL represent an abnormally large proportion of either "T" or "B" lymphocytes.<sup>172</sup>

Anergy and loss of lymphocyte transformation are frequent in Hodgkin's disease.<sup>51,78</sup> Lymphocytes from patients with HD produce an abnormally large amount of

lymphotoxin in the absence of stimulation and an abnormally small amount when stimulated.<sup>189</sup> This could be interpreted as indicating that the lymphocytes may be abnormal in this disease. Alternatively, a specific lymphocyte compartment may be suppressed by the disease, as suggested by the fact that many anergic patients are lymphopenic. It would appear that loss of cellular immunity is selective, since circulating immunoglobulins are not usually reduced in HD.<sup>74</sup> Many investigators have assumed that the Reed-Sternberg cells and other histiocytes of HD are the "malignant" cells. However, except for the peculiar morphologic appearance of Reed-Sternberg cells, there are no data that define their characteristics except that they do not synthesize DNA (Chapter 50).

Normal immunoglobulins and immunoglobulin production in response to antigenic stimulation are reduced in myeloma. However, since normal immunoglobulins may increase in patients otherwise improved by chemotherapy<sup>54</sup> it is possible that the paraprotein acts as a suppressant. The frequently bizarre morphologic appearance of the myeloma cell suggests that it may be an abnormal cell, as does the abnormal pattern of methylation of tRNA.<sup>101</sup>

### Acute Leukemias

Many studies of cellular abnormality have focused on the acute leukemias.<sup>69, 118, 165, 211</sup> However, except for the PHA-transformed lymphoblast, comparison with normal cells is difficult since populations of normal "blasts" are not readily available. Consequently, whether biochemical differences between "leukemic" and normal leukocytes reflect true abnormalities of leukemic cells, or simply cellular immaturity, is difficult to determine. An RNA-dependent DNA polymerase is found in leukemic lymphoblasts and has not been unequivocally demonstrated in normal cells (page 1454). Both humoral and cell-associated immune mechanisms appear intact in ALL,<sup>92</sup> suggesting that the lymphoblastic proliferation neither represses nor replaces the normal immunocytic system.

The blasts of acute myeloblastic leukemia

often are abnormal in morphologic appearance. This is especially true of variants such as those present in myelomonoblastic leukemia and erythroleukemia. When some cytoplasmic maturation occurs it may follow an abnormal pattern such as the formation of *Auer rods*, an abnormality seen also, though rarely, in CML. These pink-staining, round, rod, or string-like cytoplasmic inclusions apparently are aberrant forms of azurophilic granules.<sup>103</sup>

Gavosto and associates<sup>107</sup> demonstrated decreased rates of protein synthesis in leukemic as compared to normal blasts. Evidence for *impairment of protein synthesis* in human acute leukemic blast cells was summarized by Gallo<sup>106</sup>: (1) there is direct evidence that protein synthesis is impaired in some leukemic blast cells as compared to normal blasts; (2) inappropriately methylated RNA precursors accumulate in leukemic cells and also in normal cells treated with protein synthesis inhibitors; (3) there are qualitative and quantitative differences in certain tRNA's in leukemic compared to normal blast cells which could cause or could be the result of impaired protein synthesis; (4) circular DNA dimers, found in leukemic, but not normal cells, can be induced in normal cells by inhibition of protein synthesis; (5) in leukemic cells, DNA synthesis and generation time are similar to or less rapid than those of normal cells and defective protein synthesis may impair DNA synthesis; (6) chloramphenicol is a potent inhibitor of mitochondrial protein synthesis and acute leukemia may follow chloramphenicol-induced aplastic anemia; however, (7) in many instances, morphologic and biochemical characteristics are similar in leukemic and in normal blast cells.

### Other Abnormalities

Regulatory mechanisms of cell differentiation may be recognized by measuring tRNA.<sup>75</sup> In stable cell systems, species specific tRNA methylase causes a highly reproducible sequence of methylation of tRNA, and quantitative and qualitative alterations in tRNA methylation occur in differentiating as

opposed to stable cell systems. That changes in tRNA methylation rate and sequence may have some relationship to cancer is suggested by the observation that certain alkylating carcinogens alkylate tRNA even more prominently than DNA.<sup>75</sup> Alterations in tRNA methylase specificity and tRNA methylase capacity have been demonstrated in a variety of neoplastic tissues, as compared to their normal counterparts, including those of human leukemia, Burkitt's lymphoma, myeloma, adenocarcinoma, and breast carcinoma. A species of phenylalanine tRNA, thought to be related to embryonic tRNA, was found in spleens from patients with CML, but not in normal spleens.<sup>154</sup>

Cells from the marrow of patients with AML may grow in culture, but, in general, just as *in vivo*, they fail to mature *in vitro*.<sup>77,88,111a,177</sup> This suggests that the defect responsible for lack of cellular maturation is found in the leukemic cell rather than in the environment of the leukemic host. However, other observations suggest that the question of cellular versus environmental abnormality<sup>146</sup> is unsettled. Thus, murine leukemic myeloblasts have been observed to mature *in vitro*, while failing to do so *in vivo*, and some *in vitro* maturation has been reported for human leukemic cells.<sup>97</sup> The few neutrophils that do mature in AML appear to be normal with respect to migration into exudates<sup>71</sup> and phagocytosis, but may be deficient in alkaline phosphatase activity.<sup>84</sup> From a functional viewpoint, cells in CML also probably are normal. Mature CML cells migrate normally into exudates<sup>71,73</sup> and are found to be efficient phagocytes when studies that correct for the number of immature cells are performed.<sup>84</sup> In most patients the Ph<sup>1</sup> chromosome is present in virtually all cells (page 1441) and leukocyte alkaline phosphatase is reduced in mature neutrophils (Chapter 48). Evidence for a membrane difference between mature neutrophils from normal persons and from patients with CML has been presented.<sup>60</sup>

A number of animal tumors contain a tumor-specific antigen, not demonstrably shared by any normal host cell and probably related to oncogenic viruses.<sup>79,141</sup> A search for tumor-specific antigen in leukemia has

sometimes been entirely unproductive,<sup>183</sup> but evidence for a neoantigen in leukemic cells has been offered. Lymphocytes from non-leukemic monozygotic twins recognized the lymphoblasts of their leukemic twin as foreign<sup>142</sup> and lymphocytes from patients in remission underwent blastic transformation when exposed to autologous leukemic cells.<sup>114</sup> Naturally occurring cytotoxic antibodies, apparently specific for leukemic cells, have been found in serum from normal persons and from relatives of leukemic patients,<sup>65</sup> and seemingly specific antisera against various types of leukemic cells have been produced by injecting the cells into primates<sup>150</sup> or by injecting Burkitt's lymphoma cells into rabbits.<sup>115,145</sup> Antisera prepared against lymph nodes from patients with Hodgkin's disease and absorbed by normal splenic tissue reacted with nodes from other patients with HD, but not with normal nodes, suggesting the presence of a tumor-specific antigen.<sup>159,161</sup> A few patients with lymphoma have carcino-embryonic antigen in their serum, an antigen common to several varieties of neoplasm.<sup>89,108</sup> By immunodiffusion techniques, but not by immunofluorescent techniques, CML cells were found to contain an antigen not demonstrable on CLL or normal leukocytes.<sup>220</sup>

### Cell Kinetics

In neoplastic diseases of the hematopoietic system there is an increase in the size of one or more *cellular compartments*; there may be an increase in an isolated subcompartment such as a lymphomatous lymph node or in a total body compartment as in leukemia patients and in most patients with myeloma. Compartment size represents the balance between cell inflow and/or cell division and cell loss by maturation or death. Thus, these tumors theoretically can be explained by increased cell reproduction, increased life span in the compartment, or combinations of the two.

The rate of cell reproduction is a function of three variables: (1) potential number of dividing cells in the compartment; (2) pro-

portion of those that are in a generative cycle; and (3) duration of the generative cycle. In the leukemias these parameters have been defined to some degree by means of tritiated thymidine-labeling studies.

The proportion of cells in a generative cycle usually has been found to be normal or slightly decreased in CML<sup>84,109</sup> and decreased in the acute leukemias<sup>140,191</sup> and in CLL.<sup>190</sup> In CML, the proportion of promyelocytes and myelocytes in cycle was found to be normal, while the cycling proportion of myeloblasts was decreased.<sup>84</sup> Estimated generation times have likewise been normal or longer than normal. From such studies, earlier concepts suggesting that leukemia is characterized by abnormally rapid cell proliferation have proved incorrect. However, uric acid excretion, which is a rough measure of the rate of overall cell turnover, is high in CML and the acute leukemias, but usually is normal in CLL.<sup>185</sup> From this as well as from estimations of the total number of dividing cells<sup>84,140</sup> it is apparent that overall cell production is increased in CML and in the acute leukemias. The increased cell production reflects an increase in the size of the potentially dividing compartment and is accomplished with a normal or subnormal proportion of the compartment in a generative cycle of normal or abnormally long duration. Whether total cell production is normal, subnormal, or slightly increased in the average patient with CLL cannot be determined from present data. However, careful kinetic analysis of data in two patients with "typical" disease revealed an overall increase in lymphocyte production.<sup>208a</sup>

The *life span* of leukemic cells also may be prolonged. In CLL there is evidence that the small lymphocyte has an abnormally long intermitotic interval, complementing data indicating that a reduced proportion of the compartment is in a generative cycle.<sup>190</sup> The life span of the lymphocytes, as measured by chromium labeling, is suggestively prolonged.<sup>221</sup> In CML, blood-labeling curves with  $^{51}\text{Cr}$ ,<sup>195</sup> or  $^{3}\text{H}$ <sup>84</sup> are quite prolonged. However, whether overall survival time from formation of the myeloblast

to loss of the mature PMN is prolonged is less certain.<sup>55,73,84</sup> The abnormal cell-flow patterns and distribution in CML (see below) complicate the interpretation of blood-leukocyte disappearance curves. A normal "life span" is difficult to assign to normal myeloblasts or lymphoblasts since they ordinarily divide again or mature rather than remain static in the compartment. Survival time for leukemic lymphoblasts and myeloblasts has not been well established. However, the studies of Mauer and coworkers<sup>140</sup> and of others suggest that leukemic blasts can move from a dividing compartment to a resting compartment only to again enter the dividing compartment some time later. This concept of "resting" leukemic blasts is important in designing chemotherapy schedules and is considered further in Chapter 55.

In addition to abnormalities of production rate and perhaps of cell life span, cells are *abnormally distributed* in the leukemias. In CLL, the proportion of lymphocytes that are normally recirculating (Chapter 7) is reduced and/or the time required for recirculation is prolonged<sup>76,121</sup>; output of cells from the thoracic duct is less than normal.<sup>66,190</sup> In CML, myeloid cells are produced in the spleen as well as the marrow and at times in the liver and other organs.<sup>84</sup> The undefined barrier (Chapter 2) to the escape of immature cells from the marrow is altered so that immature as well as increased numbers of mature cells are found in the blood. In a few patients observed by us in very early stages of CML, few or no immature cells appeared in the blood until the leukocyte concentration reached approximately  $50 \times 10^9/l$ , suggesting that loss of the barrier is a secondary rather than a primary pathogenetic mechanism. The normal flow of neutrophils is a one-way street, from marrow to blood to tissues or body cavities (Chapter 6). In CML, on the other hand, both mature and immature neutrophils may reverse the flow and reenter the marrow.<sup>84</sup> Furthermore, traffic between the blood and splenic tissue appears brisk. In the acute leukemias, cell production may occur in virtually any body organ (Chapters 47 and 54), but is most regularly found in

the spleen, liver, and lymph nodes in addition to marrow. In certain patients the barrier to immature cell release is intact and blasts are rare in the blood (aleukemic leukemia, Chapter 47), but in most patients it is not. Little is known concerning the traffic of blasts between blood and tissues,<sup>140</sup> but it is clear that blasts in AML may return to marrow from blood.<sup>135</sup>

*Dissociation between nuclear and cytoplasmic maturation* also may occur; "immature" CML cells may be phagocytic, in contrast to their normal counterparts.<sup>216</sup>

Thus, a variety of kinetic defects has been demonstrated in the leukemias. The cellular accumulation in blood and tissues reflects the summation of these defects.

The kinetics of the tumor cells in myeloma<sup>208</sup> and in the lymphomas<sup>158</sup> suggests that these are slowly growing tumors. However, the growth kinetics of normal cells, which are comparable to the tumor cells in these diseases, has not been measured. Consequently, one cannot be certain whether their growth rate is faster or slower than normal.

### Control Mechanisms

As noted in Chapters 2, 6, and 7, our understanding of how the compartment size of leukocytes is controlled is quite incomplete as compared to that of red cells (Chapter 4) or even platelets (Chapter 9). As a result, the long-standing hypotheses that leukemia, and for that matter lymphoma and myeloma, may be due to excessive levels of cell-growth stimulators, decreased levels of inhibitors, or other factors have not really been tested. There are some data, however, that bear on the question of maintenance of normal control.

As previously mentioned (page 1446), levels of normal immunoglobulin have improved following treatment of some patients with myeloma. This suggests that control mechanisms of immunoglobulin level (Chapter 7) are intact in myeloma and, if this is true, indicates that production of the myeloma protein is not subject to this normal control.

A factor that stimulates the growth of granulocytic colonies *in vitro* (colony-stimulating factor, CSF) can be demonstrated in normal human urine, plasma, and leukocytes.<sup>82,118</sup> Whether the substance is active *in vivo* or of physiologic significance remains to be determined. However, if CSF should prove to be a true neutropoietin, its progressive increase as the leukocyte count rises in CML,<sup>176</sup> its absence from some leukemic leukocytes,<sup>113</sup> and its erratic increase in acute leukemia<sup>102,148</sup> suggest abnormal and often physiologically inappropriate production of CSF in leukemia.<sup>146</sup>

Lymphocyte compartment size is controlled, at least in part, by the degree of antigenic stimulation (Chapter 7). Since patients with CLL, NHL, or HD often are unresponsive to such stimulation, some form of faulty control must be assumed.

## Etiology

The cause of leukemia or of lymphoma is unknown. However, certain factors that influence the frequency of development of these diseases in the population at large have been identified and a great deal has been learned concerning the cause of seemingly analogous diseases in animals.

Theories concerning the nature of leukemia, as well as cancer in general, can be divided into two broad categories: (1) the cell causing these diseases is intrinsically abnormal and all progeny of such cells must also be abnormal; (2) the cell is abnormal by virtue of its environment, and external influences lead to an abnormal pattern of growth.

In either case the disease could be clonal, i.e., the abnormality could begin in a single cell and the disease might be the product of that single cell (unicentric origin), or the abnormality could begin or be induced in more than one cell (multicentric). These and related topics have been discussed, under the heading "pathogenesis" (page 1440).

It is possible that these diseases do not have a demonstrable etiologic basis. Random genetic aberrations may occur in all dividing-cell systems, assuming that they are clonal.

When an aberration is viable and confers a selected advantage for growth as compared to normal cells, a tumor may result.

The causes of these diseases may differ; indeed, the observation that irradiation increases the frequency of certain leukemias but not others (page 1456) strongly supports this view.

## Viruses

The possibility that leukemia and lymphoma are due to infection was raised almost concurrently with their initial description. Indeed, CML can be mimicked by certain infections (Chapters 41 and 48); the granulomatous nature of HD certainly suggests a reaction to some organism. However, to date no organism has been clearly shown to have an etiologic association with hematopoietic neoplasia in man.

There is now no doubt that leukemia and lymphoma in mice, fowl, and probably various other species require the presence of a virus for their clinical expression.<sup>250,272,283</sup> In 1903, Borrel<sup>233</sup> suggested that cancer is due to a virus and, in 1909, Ellerman and Bang<sup>241</sup> demonstrated that fowl leukosis could be transmitted by a sub-(light) microscopic, filterable particle. Shortly thereafter, Rous described virus-induced sarcoma.<sup>282</sup> It was almost 50 years before the studies of Gross,<sup>219</sup> Friend, and others provided unequivocal data that a variety of animal leukemias are intimately and etiologically related to viruses.<sup>283</sup>

Leukemia in the laboratory mouse has become the classic model. In certain strains, leukemogenic virus is passed to offspring via infected ovum. Some data also implicate infected sperm.<sup>234</sup> The virus is introduced into newborn mice who suckle from mothers harboring the virus. Passage of virus to older normal mice, however, is quite difficult; consequently, evidence for "infectivity" in the usual sense with spread by respiratory, oral, or vector routes is tenuous. The data suggest that the virus is present in utero or early infancy rather than being acquired in later life. Yet, the incidence of leukemia in strains of mice harboring leukemogenic viruses differs. In some, the frequency of death from

old age or other causes far exceeds death from leukemia. Others, such as the AKR strain, usually will die of leukemia. Induction of viral-induced murine leukemia can be hastened by such factors as irradiation, immune system damage, or chemical leukemogens.<sup>251</sup> Thus, the mouse model suggests that the presence of virus is essential, but various genetic and environmental factors alter the rate of its expression.<sup>266</sup>

Viruses are distinguished according to whether the primary nucleic acid constituent is RNA or DNA. Most animal leukemia viruses are RNA viruses.<sup>283</sup> A particle ("*C*"-type particle) identifiable by electron microscopy has been shown to represent an RNA-type leukemia virus (oncornavirus) in one stage of development (page 1452). In the marrow of leukemic mice this type of particle often is abundant in megakaryocytes, but may be scant in leukocytes. At certain stages of disease it can be obtained from plasma by differential centrifugation.

### Explanations of RNA Virus Action

To explain RNA virus action, Temin<sup>287</sup> proposed that viral RNA can be converted to cellular DNA (*pro-virus*) by transcription and remain as part of that cell's genetic information, including the potential to produce more virus. Such conversion would presumably require an enzyme capable of translating RNA into DNA. He then demonstrated the presence of RNA-dependent DNA polymerase in Rous sarcoma tissue; Baltimore demonstrated it in Rauscher leukemia.<sup>290</sup> Temin showed that the Rous sarcoma virus can make a DNA copy of itself and that the DNA copy is a template for synthesis of new virus. Thus, genetic information, originating from RNA, is incorporated in the cell (*reverse transcription*).

At least 15 tumor viruses have now been shown to contain reverse transcriptase.<sup>283</sup> Thus, at least part of Temin's "provirus" hypothesis appears to be correct. In theory, once a cell has been infected and the viral information has been converted into DNA, reverse transcriptase is no longer necessary

because the provirus will be duplicated during DNA synthesis in the generative cycle and passed to daughter cells produced by mitosis. The "*oncogene*" theory of Huebner and Todaro,<sup>257</sup> on the other hand, suggests that the genetic component of most, if not all, vertebrates contains information for production of RNA-tumor viruses. Viral information ("*virogene*") and the portion of the viral information responsible for inducing malignant transformation of the cell ("*oncogene*") are inherited "vertically," but normally are repressed. Derepression of the "*oncogene*" may be the result of toxic insult (chemical carcinogens, irradiation, etc.), aging, or infection with other viruses or other factors and results in malignant cellular transformation. The "*oncogene*" could be derepressed, but the complete "*virogene*," necessary for viral reproduction, might not be derepressed and, consequently, viral particles might not be present. Temin's<sup>288,289</sup> "*proto-virus*" theory (not to be confused with his somewhat complementary "provirus" theory discussed above) is similar to the "*oncogene*" theory in that information for cancer (provirus) is transmitted vertically. It differs from the oncogene theory in postulating that proviruses play a role in normal cellular differentiation; that, at some stage in normal cellular differentiation, reverse transcriptase plays a role; and that, for the provirus to induce cancer, somatic mutation must lead to a modification of RNA, DNA, or reverse transcriptase. While certain data tend to support either the oncogene or provirus theory,<sup>283</sup> further studies are required to determine whether either is correct as presently formulated. It may be pointed out that these theories are compatible with either a clonal or a multicentric origin of hematologic tumors; that is, the event leading to the expression of viral tumorigenesis may begin in a single cell with subsequent proliferation of that cell, leading to a clonal tumor, or it may begin in many cells concurrently and lead to similar chromosomal and/or enzymatic changes in all affected cells so that they would be inferred, incorrectly, to be the progeny of a single, transformed cell.

Leukemia occurring spontaneously in mice and that induced by transplanting leukemic cells are both virus-related. Transplanted murine leukemia can be cured by a variety of cell-killing chemicals, while spontaneous leukemia is much more resistant. One explanation for this difference would be to suggest that, in transplanted leukemia, the virus, at least as reflected by viral replication, does not persist, while in spontaneous leukemia the virus persists and replicates, perhaps in cells other than those identified as leukemic, and reinfects the "leukemic" cells after therapy. Subtle antigenic differences between host and transplanted cells could represent alternative explanations for this difference between the responses of spontaneous and transplanted leukemia to therapy.

#### **Evidence for Viruses as Etiologic Factors in Leukemia and Lymphoma in Man<sup>224,233</sup>**

The unequivocal evidence of an etiologic relationship of virus to tumors in many species of lower animals strongly suggests the possibility of such a relationship in these diseases in man. However, despite intensive studies designed to demonstrate a viral agent in leukemia and lymphoma in man, conclusive evidence has not been forthcoming. The search for a human leukemia virus has centered around the following types of studies: attempts to demonstrate by electromicroscopy virus-like particles in human tissue or plasma, the possible emergence of virus in human cell lines in tissue culture; attempts to transmit disease by injecting cell-free human material into lower animals; and the identification of RNA-dependent DNA polymerase in human leukemic tissue.

#### ***Virus-like Particles in Patients with Leukemia and Lymphoma***

Particles resembling murine leukemia viruses, "C-type particles," have been reported in leukemic or lymphomatous cells examined by electron microscopy.<sup>239,295</sup> However, such particles have been quite sparse, and were

found in only a small proportion of the specimens examined. As the science of electron microscopy has evolved, the need for thin sections in order to avoid artifacts resembling such particles has been recognized and a number of investigators now consider earlier reports based on thick sections to be uninterpretable.<sup>280</sup> Using thin-section techniques, particles strongly resembling animal tumor virus, including "budding" in C-type particles, have been reported,<sup>239,295</sup> but careful surveys of tissue by other workers have failed to reveal such particles.<sup>278,280</sup>

When it was found that tailed, "C-type particles" could be spun from cell-free plasma of mice and other animals with virus-induced leukemia,<sup>227</sup> excitement was engendered by the identification of particles resembling C-type particles in spun plasma or urine pellets of patients with leukemia.<sup>229,262</sup> However, other studies<sup>235,274</sup> failed to disclose a higher incidence of such pellets in patients with leukemia as compared to that in controls. It is possible that the structures in question may be organelles of ruptured, normal blood cells.<sup>231,278</sup>

#### ***Virus in Cell Cultures***

Although other viruses have not been seen in many long-term cultures of lymphocytoid cells derived from patients with leukemia,<sup>252</sup> a herpes-like virus (the Epstein-Barr [EB] virus) has been demonstrated in cell cultures from many patients with Burkitt's lymphoma,<sup>235,242,253</sup> and in cell lines from patients with leukemia or with various cancers, as well as in cultures of presumably normal cells.<sup>273</sup> Even when herpes virus has not been seen in established lymphoid cultures, its presence could be inferred in most, if not all cultures, by means of antibody studies.<sup>284</sup> In fact, the most reliable means of establishing long-term cultures of normal lymphoid cells is to infect the cells with EB virus.<sup>245</sup> Thus, in a sense, the virus confers a "malignant" growth potential on normal cells. It stimulates DNA synthesis in infected cells, a property shared only by known oncogenic DNA viruses insofar as is known

presently.<sup>284</sup> Conceivably, this effect might be mediated by derepressing "proviral oncogenes" (page 1451) already present in the cell.

There is serologic evidence for the widespread distribution of the EB virus in the general population. In patients with Burkitt's lymphoma, including both African and American patients, antiviral titers almost always are present and the titers are quite high.<sup>254,264,284</sup> The EB virus appears to be the cause of infectious mononucleosis<sup>254,275,286</sup> (Chapter 43). While its etiologic role in Burkitt's lymphoma is not proved,<sup>276</sup> it may be asked whether the same virus can cause malignant and benign disease in different populations. In this regard it has been demonstrated that expression of infection with the murine, Friend leukemia virus is under the control of specific genetic loci.<sup>277</sup> Additional observations of possible significance are the fact that a cell line that produces tumors in hamsters has been derived from a cell culture originally obtained from a patient with infectious mononucleosis<sup>223</sup>; and that inoculation of a herpes virus induces a lymphoma-like illness in marmosets and lymphoblastic leukemia in owl monkeys.<sup>222,268</sup>

There is a higher than normal frequency of serologic evidence for EB virus infection in patients with lymphoblastic leukemia and lymphomas other than Burkitt's, but not in patients with CLL. However, neither the frequency nor the height of the titer approaches that seen in patients with Burkitt's lymphoma.<sup>263,269</sup> The development of infectious mononucleosis during the course of ALL<sup>269,285</sup> makes it most unlikely that EB virus causes ALL. It was suggested that a preceding infection with EB virus might somehow "trigger" the subsequent development of ALL.<sup>265</sup> However, a comparison of the frequency with which leukemia or lymphoma developed in veterans who did or did not have infectious mononucleosis during World War II revealed no differences between the groups.<sup>271</sup> An increased frequency of antibodies to herpes virus hominus type 2 has been reported in patients with HD.<sup>236</sup> The demonstration of an unidentified herpes-type virus in a culture of lymph nodes from

patients with HD<sup>240</sup> is still another intriguing, but as yet unproven, piece of evidence that these DNA viruses may play some role in neoplasia in man.

### Antiviral Antisera

The cellular specificity of antisera, prepared against known oncogenic viruses, provides indirect evidence for the viral origin of leukemia. Immunofluorescent antisera prepared against "pellets" from plasma of leukemic patients labeled leukemic, but not normal, leukocytes. The spectrum of activity of this plasma was quite similar to that of immunofluorescent antibody prepared against Rauscher murine leukemia virus.<sup>230</sup> Absorption of antipellet antibody with normal leukocytes did not remove the antibody's ability to label leukemic cells, but repeated absorption with normal bone marrow did,<sup>296</sup> suggesting that the antigenic difference reflected a difference between mature and immature cells rather than a tumor-specific antigen. Furthermore, anti-Rauscher leukemia virus antibody labels cells from patients with a wide variety of nonmalignant hematologic diseases.<sup>244,258</sup> Mice injected with Rauscher or Friend leukemia virus developed new cellular antigens in skin as well as leukemic cells.<sup>267</sup> These antigens were acquired whether or not the animal was susceptible to leukemia.

### Attempts to Induce Leukemia

Attempts to induce leukemia in sub-human primates by injecting adult, neonatal or in utero animals with cells or subcellular material from human leukemia or lymphoma or with viruses arising in tissue culture lines have been unsuccessful.<sup>260</sup>

### Infants Born of Leukemic Mothers

If leukemia is due to a virus, then infection of infants born of leukemic mothers would seem almost certain since most, if not all, human viruses cross the placenta, as does the murine leukemia virus.<sup>224</sup> Leukemia has de-

veloped in at least three children born of leukemic mothers,<sup>272,238</sup> but adequate follow-up of a series of such children has not been reported.<sup>229</sup> Passage of leukemic cells across the placenta has been suggested,<sup>279</sup> but quinacrine, the compound used as a cell label, elutes from leukocytes and, consequently, interpretation of the reported data is difficult.

### Transfusion of Cells from Patients with Leukemia

Leukemia has not been induced by transfusion of cells from patients with leukemia to nonleukemic subjects.<sup>247,291</sup> When large numbers of cells from patients with CML have been transfused into neutropenic patients with acute leukemia, transient engraftment of CML cells has been noted.<sup>186</sup> Considering our present knowledge of tissue transplantation in man and the nature of viral transmission in animals, these short-term observations are basically uninterpretable with respect to the etiologic background of leukemia.

*Transmission of human leukemia to normal human cells* has apparently occurred in two instances.<sup>273</sup> Children with leukemia were given total body irradiation, and marrow from a normal sibling of the opposite sex was transplanted. Leukemia recurred but the leukemic cells had the chromosome constitution of the donor, suggesting that the cell graft had acquired leukemia.

### Reverse Transcriptase in Human Tumors

Gallo and associates were the first to demonstrate reverse transcriptase (page 1451) in the blood cells of some patients with acute leukemia.<sup>283</sup> In their studies the enzyme found in the blood cells of these patients met all of the biochemical criteria for a true reverse transcriptase, whereas enzymes isolated from normal cells have not met these criteria.<sup>283</sup> For example, an enzyme from PHA-stimulated normal lymphocytes proved to be an RNA-primed, but DNA-directed

DNA polymerase rather than a reverse transcriptase. The reverse transcriptase may be derived from a tumor virus. An antibody against type C virus reverse transcriptase derived from sub-human primate sarcoma has been found to react with reverse transcriptase from human leukemia.<sup>283</sup> The human transcriptase produces DNA with some sequence homology to viral RNA of simian and murine sarcoma virus, as judged by hybridization studies.<sup>283</sup>

### Other Infecting Agents

The granuloma-like pathologic picture that is seen in HD led to an intensive search for organisms such as the tubercle bacillus in patients with this disease.<sup>256</sup> Although some positive reports appeared, to date there has been no convincing evidence of the association of any organism with such granulomas.

Some of the "viruses" isolated from leukemic tissue have proved to be mycoplasmas on further study.<sup>243,246</sup> In general, these have been thought to be secondary invaders of cell cultures rather than etiologically related to the disease.<sup>243,246</sup> Attempts to link leukemia and lymphoma in human beings to disease in pets have generally been unfruitful.<sup>405</sup>

### "Clustering" of Patients with Leukemia, Lymphoma, and Myeloma

If leukemia or lymphoma is induced by a communicable infectious agent or by some environmental factor that is not uniformly distributed, then a nonrandom distribution of cases in time and space would be expected. Apparent epidemics have been reported,<sup>343,363,402</sup> such as the development of acute leukemia in eight fairly closely associated children in Niles, Illinois, between 1957 and 1960,<sup>343</sup> and Hodgkin's disease occurring in 31 persons who could be interlinked by personal contact in one way or another, many of them through a New York high school.<sup>402</sup> However, the statistical significance of such reports is questionable. In this regard the

quotation from Plutarch cited by Ederer et al.<sup>324</sup> seems most applicable: "It is no great wonder if in long process of time, while fortune takes her course hither and thither, numerous coincidences should spontaneously occur."

In an attempt to determine if clustering does occur, the distribution of patients with leukemia in relation to known population density and the time of onset of disease in different cases with respect to one another, to season of the year, or to month of birth of the patients have been studied. The statistical methods of such studies, however, are complex and imperfect.<sup>323,333</sup> Some evidence for time-space clustering of leukemia has been obtained in Buffalo<sup>388</sup>; Northumberland and Durham<sup>364</sup>; Cornwall<sup>406</sup>; Liverpool<sup>376</sup>; urban, but not rural, Manitoba<sup>335</sup>; in children under six, but not older children<sup>333</sup> or adults,<sup>311</sup> in New Zealand; in children under six, but not in older children, in London<sup>399</sup>; in children, but not adults, in Georgia,<sup>325</sup> and in Portland, Oregon, but not in the state of Oregon as a whole.<sup>363</sup> Little or no evidence for time-space clustering of leukemia was obtained for San Francisco<sup>362</sup> and Connecticut,<sup>305,324</sup> but there was evidence for lymphoma clusters in Connecticut. No tendency for clustering of leukemia was detected in upper New York State,<sup>329</sup> Hawaii,<sup>367</sup> or Los Angeles.<sup>332</sup> Clustering in time and space has been reported for myeloma in Minnesota.<sup>365</sup>

Literature seeking to relate the month of the year to the onset of leukemia<sup>342,368</sup> or HD<sup>317</sup> is quite confusing. Certain studies have reported higher onset rates in certain seasons, but the peak season has differed from one study to another. Some studies suggest that the month of birth has some relation to the frequency of leukemia in the first few years of life,<sup>323,342,368</sup> but no such relation was detected in others.<sup>306,376,395,399</sup>

In summary, the literature dealing specifically with leukemia clustering is equivocal. Taken as a whole, it suggests that there may be a slight tendency for leukemia in children to cluster in time and space, but such a tendency seems limited to densely populated

urban areas. In a negative sense, the absence of strong clustering tendencies suggests that leukemia is not a communicable disease, at least as we commonly think of such diseases.

Examination of space distribution of United States mortality statistics<sup>34</sup> lends some support to a mild tendency for hematologic neoplasms to cluster. For instance, acute leukemia is significantly more common in New York and New England than in the Southeast. To some degree this probably reflects reporting accuracy since most of these diseases are more frequent in the Northeast and less common in the Southeast. However, it is difficult to apply this explanation to all differences since acute leukemia is also reported at less than average rates from the Midwest, while lymphoma and myeloma are reported at greater than average rates from the same region.

Clustering in space of Burkitt's lymphoma (Chapter 51) is most remarkable.<sup>235,311,312</sup> This tumor is found in a belt across Central Africa and, with the exception of New Guinea,<sup>28</sup> tumors of similar pathologic appearance, age incidence, and response to therapy have rarely been observed elsewhere. The increased frequency of Burkitt's lymphoma correlates very well with a median annual temperature above 60°F and median annual rainfall exceeding 20 inches. Tribal origin does not appear to be a factor in incidence. As noted on page 1452, there is some evidence for an association with a herpes virus and, since the climatic limits of the disease duplicate those of certain strains of mosquitos and flies, a vector-borne infection also has been suggested.

### Other Environmental Factors

As will be noted, a variety of environmental factors have been suggested as influencing the frequency of leukemia, lymphoma, and myeloma. However, with the exception of gamma irradiation and benzol and related hydrocarbons, no firm relationship of such factors to disease has been established.

Table 46-4. Irradiation Exposure and the Risk of Developing Leukemia

Type of Exposure	Leukemia Risk* (Frequency/Control Population)
Survivors of atomic bomb <sup>152</sup>	
Hiroshima	
> 100 rads exposure	23 6
5-99 rads exposure	3 7
Nagasaki	
> 100 rads exposure	10 3
5-99 rads exposure	< 1 0
Radiologists <sup>179</sup>	2 5
Patients receiving radiotherapy	
Ankylosing spondylitis	
> 2 000 rads	14 4
< 500 rads	4 2
Polycythemia vera	
<sup>32</sup> Phosphorus x-irradiation	13 7
	11 1
Chronic lymphocytic leukemia	
<sup>32</sup> Phosphorus	3 2
Thymic enlargement	71 0
Cancer of cervix <sup>150</sup>	71 0
Hyperthyroidism <sup>100</sup>	71 0
Diagnostic irradiation	
In utero	71 5
Postnatal	71 0

\*Calculated from data published by Lillienfeld<sup>179</sup> except where otherwise indicated. Insofar as possible, risk figures were derived from a control population with the same disease rather than from the general population.

## Irradiation

Exposure to gamma irradiation in appreciable doses leads to an increase in the frequency of CML and AML and perhaps ALL. There is some evidence to indicate that irradiation exposure may also induce small-cell LSA, HD, and myeloma, but, as yet, there is no evidence of any relation between irradiation and CLL or histiocytic lymphoma. Data upon which these conclusions are based, derived from surveys of survivors of atomic blasts, patients with various diseases treated

by irradiation, and radiologists exposed to irradiation, reflect the risk of developing leukemia following various forms and doses of irradiation. These are summarized in Table 46-4.

## Survivors of Atomic Blasts

Periodic surveys of the survivors of the atomic blasts in Hiroshima and Nagasaki have revealed a clear excess of leukemia, most notably CML and AML and probably ALL, but not CLL.<sup>306,309,318,343,352,374</sup> The incidence of leukemia has varied inversely with the survivor's distance from the blast hypocenter and directly with the calculated whole body dose (Table 46-4). When distance increased to the point that the calculated dose was reduced to less than 5 rads, the incidence of leukemia could not be distinguished statistically from that in unexposed populations. However, there is no clear evidence for a threshold exposure below which there is no increase in incidence.<sup>352</sup> The fact that the frequency of leukemia has been less in Nagasaki than in Hiroshima (Table 46-4) may reflect differences in type of irradiation, such as a lesser leukemogenic effect of neutron as compared to gamma irradiation, since the bomb directed at Nagasaki had a much higher neutron:gamma emission ratio than did that falling on Hiroshima.<sup>352</sup> It is of some interest with respect to the possible role of irradiation in leukemia in general that the course and clinical behavior of leukemia in A-bomb survivors have not been unusual; those with CML usually have had the Ph<sup>1</sup> chromosome and in those with acute leukemia the chromosome changes were fairly typical.<sup>360</sup> The peak incidence of disease probably occurred six to seven years after the blast, but an increased incidence as compared with that in a normal population has persisted for more than 20 years.<sup>374</sup> The rate of decline in incidence appears to be slower in those lightly than in those heavily exposed.<sup>369</sup> It has been suggested that this may be attributable to occupational exposure to benzol and to x ray.<sup>353</sup> No excess of leukemia has been found in children born of exposed survivors.<sup>346,354</sup>

Lymphosarcoma, HD, and myeloma also have been suggestively more frequent in heavily exposed survivors, but histiocytic lymphoma and CLL, the latter being a disease which is rare in Orientals (page 1461), have not.<sup>301</sup>

Chromosome changes are demonstrable in a minor population of lymphocytes in apparently healthy survivors, as they also are in patients exposed to total body irradiation.<sup>302</sup>

### *Patients Treated by Radiotherapy*

The terminal phase of polycythemia vera (Chapter 30) may resemble AML or CML, even if phlebotomy has been used for the treatment of the polycythemia. However, such a terminal leukemic picture is more frequent if x ray or <sup>32</sup>P therapy has been employed,<sup>179</sup> and there is a roughly linear relationship between the total dose of <sup>32</sup>P and the frequency of terminal leukemia. Chronic lymphocytic leukemia (Chapter 50) rarely, if ever, terminates in an acute phase unless large doses of irradiation have been employed in the treatment, and, in such patients, as in most of those with irradiation-induced leukemia, AML is observed.<sup>389</sup> Similarly, most HD patients who have developed a leukemic picture have been heavily irradiated.<sup>313,398</sup> It must be emphasized, however, that the development of leukemia after irradiation therapy is strongly influenced by the nature of the disease for which irradiation was given. The frequency of acute leukemia has been much higher in patients with polycythemia vera than in those with CLL even when both groups of patients received the same amount of <sup>32</sup>P.<sup>389</sup> In the reported cases of lymphosarcoma terminating in AML rather than ALL,<sup>336</sup> one suspects that radiation therapy may have been the cause, rather than natural evolution.

Although patients with rheumatic diseases may possibly be more likely to develop leukemia than the general population (page 1463), the observation of a dose-response relationship between x-ray therapy to the spine and the occurrence of leukemia in patients with ankylosing spondylitis (Table 46-4)

suggests that the x-ray therapy induced the leukemia. Local irradiation to the pelvic areas for carcinoma of the cervix<sup>350</sup> and <sup>131</sup>I irradiation of the thyroid<sup>393,400</sup> have not been associated with a significant increase in the frequency of leukemia, according to large-scale surveys. Thymic irradiation in children for enlarged thymus has been claimed to be associated with an increased frequency of leukemia,<sup>387,401</sup> but this has been disputed.<sup>335</sup> The reported cases are difficult to interpret since leukemia can occasionally begin with thymic enlargement (Chapter 54).

### *Leukemia in Radiologists*

Before the hazards of irradiation were recognized, death from leukemia was frequent among the pioneers in radiology.<sup>379</sup> With improved protective shielding the hazard has declined, but leukemia still is suggestively more frequent in radiologists than in other physicians (Table 46-4). Radiologists also have been found to acquire myeloma somewhat more frequently than do other physicians.<sup>372</sup>

### *Significance of Irradiation in the Overall Frequency of Leukemia*

If there is a "threshold" dose of irradiation below which there is no increase in frequency of leukemia, then irradiation is an interesting, but relatively insignificant, factor in the genesis of this disease. Conversely, if any excess of irradiation leads to an excess of leukemia, then attempts should be made to limit even minute amounts of irradiation exposure. Thus, studies of the relationship of small amounts of irradiation to the incidence of leukemia are of critical importance. Unfortunately, most studies have yielded equivocal results.

The incidence of the eventual development of leukemia in children whose mothers had diagnostic roentgenographic examinations while pregnant has been slightly, but seemingly significantly, more frequent than that in children whose mothers did not have these examinations during pregnancy.<sup>374</sup> (Table

46-4). Studies of the frequency of diagnostic irradiation procedures as related to the frequency of leukemia in patients so examined have yielded conflicting and, at best, equivocal data.<sup>108a,374</sup> It has been suggested that children exposed to low levels of irradiation can be divided into "susceptible" and "non-susceptible" groups as concerns irradiation leukemogenesis.<sup>310</sup> When large doses of radioactive agents, such as Thorotrast,<sup>391a</sup> were used for diagnostic purposes, a clearly increased incidence of AML and CML was observed. No relation between natural, background irradiation level, varying as much as nine-fold, and leukemia incidence was found in a survey made in Maine, New Hampshire, and Vermont.<sup>391</sup> Variability in extent of cosmic irradiation, as reflected by altitude of residence, bore no relation to frequency of leukemia.<sup>310</sup> With respect to the relation of "fallout" from nuclear explosions, the <sup>90</sup>strontium content of the bones of patients with leukemia was found to be less than normal,<sup>299</sup> perhaps reflecting changes in bone metabolism (Chapter 54). Most fallout from blasts in this country was concentrated in the Southwest, but so far no excess of leukemia has been noted in persons living in that region.<sup>74</sup>

Thus, the crucial question of a "threshold" relationship of irradiation and leukemia induction remains unanswered. Large doses of whole body irradiation (the A-bomb experience) and irradiation of leukemia-prone diseased populations (persons with polycythemia vera and perhaps other groups such as those with rheumatic diseases) are associated with an increased frequency of leukemia. The mechanism is unclear. However, if leukemia in man proves to be virus-related (page 1452), it is noteworthy that the time of onset of virus-related murine leukemia is accelerated by irradiation.<sup>250</sup> If the relation reflects an aberrant clone of cells derived from random induction of a chromosome abnormality in single cells by irradiation,<sup>311,369</sup> it is interesting that the Ph<sup>1</sup> chromosome abnormality has been reported as one of the abnormal, random findings in healthy, but irradiation-exposed, subjects (page 1441).

Unnecessary irradiation should certainly be avoided, but there is little to suggest that diagnostic, or even many therapeutic, irradiation procedures represent major factors in the induction of leukemia.

### Chemical Agents

As in persons with marrow aplasia and/or pancytopenia and in some with paroxysmal nocturnal hemoglobinuria (page 1463), AML has been observed in individuals who had been exposed to drugs alleged to produce marrow injury. Whether the resulting pancytopenia was an early manifestation of leukemia or whether the pancytopenia and the associated hematopoietic disturbance led to an increased chance of developing AML is moot. However, since certain congenital diseases of lymphatic tissue are associated with an increased incidence of lymphocytic leukemia and lymphoma (page 1463) rather than of myeloid leukemia, some support can be marshalled for the concept that a growth disorder of a specific hematopoietic tissue leads to an increase in frequency of the corresponding form of leukemia.

### Benzol

A variety of chemicals and drugs have been suggested as possible leukemogenic agents in human leukemia, but only benzol can be unequivocally implicated. Disturbances of the hematopoietic system, especially marrow aplasia with pancytopenia, in workers chronically exposed to benzol have been recognized for many years.<sup>319,377,380</sup> Of leukemia-like syndromes in such workers, Bernard and Braier found most to resemble AML.<sup>307</sup> The use of benzol in glues in the Italian shoe-manufacturing industry, which in large part was carried out in poorly ventilated private dwellings, forms the basis for the most complete data on leukemia following benzol exposure. The overwhelming predominance of AML or closely related syndromes, often preceded by periods of aplasia with pancytopenia, in such workers<sup>404</sup> provides compelling evidence for an etiologic relationship.

# Other Possible Leukemogenic Agents

As noted in Chapter 47, a period of pancytopenia with or without apparent marrow aplasia may precede the frank development of AML and related syndromes. Not only benzol but also other drugs that may cause pancytopenia have been suggested as causing AML. The rarity of case reports of chronic myelocytic or lymphocytic leukemia following exposure to such drugs, in contrast to the occurrence of AML, may be of significance. A few patients suffering from chloramphenicol-induced aplastic anemia have eventually developed AML.<sup>314</sup> Other drugs, such as hexachlorocyclohexane, have been suggested as leukemogens under similar clinical circumstances.<sup>356</sup> As noted (page 1463), the suggestion that the rheumatic diseases may be associated with an increased frequency of leukemia complicates the possible implication of phenylbutazone as a leukemogen. Phenylbutazone, which also may induce pancytopenia, has been suggestively associated with an increased frequency of AML in patients heavily treated with this drug.<sup>357</sup> The possible role of hydantoins in inducing HD is discussed in Chapter 50.

Various drugs used in cancer chemotherapy are leukemogenic in animals (Chapter 55) and it is possible that reports of acute leukemia developing in patients with myeloma,<sup>44</sup> HD,<sup>30</sup> or the cold agglutinin syndrome who had been treated with melphalan<sup>397</sup> imply such an effect.

# Miscellaneous Environmental Factors

A wide variety of environmental factors have been studied, often with conflicting findings.

Leukemia was more common in foreign-born Israeli children, especially those born in Africa, than in those born in Israel of foreign-born parents.<sup>144</sup> It was more common in both groups than in children born of parents born in Israel. The validity of the study is strengthened by the failure to show a similar association for lymphoma.

Leukemia has been reported to be less

common among the poor than among affluent groups.<sup>335</sup> However, other fairly comprehensive studies reported leukemia to be more common among the poor<sup>331</sup> and still other studies<sup>362</sup> found no relation between degree of affluence and frequency of leukemia. The last studies suggest that reports of lower frequency of leukemia in the poor may reflect less medical attention. Army inductees who developed HD were found to be from a higher economic class than those who did not develop the disease.<sup>416</sup>

Urban-rural differences in leukemia rates<sup>396</sup> can be explained, at least in part, by correction for the age of the population.<sup>380</sup> However, the finding of a higher urban than rural incidence in whites and the reverse in non-whites, and an increasing urban but decreasing rural incidence suggest that there may be true rural-urban differences.<sup>396</sup> In one study<sup>453</sup> a higher frequency of leukemia and myeloma, but not of lymphoma, was found in farmers as compared to non-farmers.

Suggestions have been made that appendectomy or tonsillectomy may predispose to the development of cancer, including leukemia and lymphoma,<sup>308,329,351,390</sup> but other studies have not substantiated such an association.<sup>340,347,358</sup>

The initial suggestion that vaccination with BCG might protect children from developing leukemia<sup>420</sup> was supported by one,<sup>391</sup> but not by a second,<sup>361</sup> large retrospective survey. Review of the incidence of leukemia and lymphoma revealed no differences between children randomly chosen to receive or not to receive BCG.<sup>418</sup>

No association of leukemia with trauma, penicillin usage, chronic infection,<sup>298</sup> influenza<sup>369</sup> or other viral infections<sup>406a</sup> in mothers, exchange transfusion in the neonatal period,<sup>321</sup> or drug history in general<sup>298</sup> was found. Children with leukemia were heavier at birth than those who did not develop leukemia,<sup>405a</sup> and certain dermatoglyphics were said to be uncommonly frequent in leukemic children.<sup>405b</sup> Greater frequency of atopic allergy in mothers of leukemic children and in leukemic children than in the general population has been claimed,<sup>378</sup> but no association

of atopy in children with leukemia was found in other studies<sup>329</sup> and a negative association also has been reported.<sup>327</sup> Whether smoking mothers do<sup>38,2</sup> or do not<sup>378</sup> have more offspring with leukemia than do non-smoking mothers is disputed. The ingestion of cold tablets has been suggested as a positive factor.<sup>379</sup> In one survey, birth order and maternal age were found to have no apparent influence,<sup>378</sup> while in another the frequency of leukemia was found to be greatest in the first-born child and in children born of older mothers.<sup>375</sup> A search for factors acting synergistically rather than as single agents revealed no increase in risk of childhood leukemia if (1) the mother had been irradiated before pregnancy, (2) had received diagnostic irradiation during pregnancy, or (3) had a history of "reproductive wastage"; or (4) the child had viral illness in early childhood.<sup>330</sup> However, when three or more of these factors were all present, the risk of leukemia was increased significantly. Leukemia has been reported in both husband and wife,<sup>300</sup> but surveys<sup>384,385</sup> suggest that such occurrences are coincidental. Psychologic factors have been considered important by some,<sup>376,371</sup> as has lightning.<sup>373</sup>

## Familial Disease

The evidence for an increased frequency of leukemia in relatives of affected patients remains in question, although more than 150 case reports of leukemia in two or more family members have appeared.<sup>124,465</sup> Miller<sup>177</sup> concluded that in siblings of leukemic children there was a four-fold increase in the risk of developing leukemia and in certain other surveys<sup>421,465</sup> a modest tendency for leukemia to be more common in relatives of patients with leukemia than in controls was observed. Others,<sup>468</sup> however, did not find this to be the case. Proper control groups for retrospective survey studies are difficult to design; the likelihood that a patient with leukemia or his parents will gain knowledge of such disease in other and distant family members is greater than would be that for control patients who are normal or suffering

from other diseases. The same statistical problems that complicate the interpretation of clustering of disease in time and space (page 1454) are applicable to isolated reports of multiple cases of disease in one family.

Perhaps part of the disagreement in the literature stems from combining all types of leukemia and related diseases rather than considering the diseases as separate entities. In many of the most impressive case reports of leukemia occurring in two or more family members, the type of leukemia was CLL, perhaps the most impressive report being that of a family in which six members developed CLL.<sup>452</sup> Gunz and Veale<sup>131</sup> found a slight excess of all types of leukemia in relatives of affected members, but considered the significance of this excess questionable for the reasons just discussed. However, using patients with CLL as indexes, they found a clear excess of CLL, CML, and perhaps lymphosarcoma and myeloma, but not of acute leukemia or other cancers in close relatives. No clear pattern of inheritance could be discerned. This survey did not include the families previously described by Gunz and associates<sup>432</sup> in which an apparent dominant pattern of inheritance was described. In another family, 9 of 29 members have an illness that resembles CML, but in some members the condition improved after splenectomy.<sup>461</sup>

Studies of concordance of leukemia in twins<sup>441,449,457,459</sup> usually, but not always,<sup>435</sup> have indicated a clear excess of acute leukemia in both twins when the twins were of the same sex. In cases concordant for leukemia,<sup>449</sup> ancillary evidence of homozygosity was found. In most reports, both twins developed the same type of acute leukemia during infancy or early childhood. No excess of leukemia was observed in non-twin siblings of children with leukemia<sup>439</sup> unless consanguinity was present in the family.<sup>443</sup> The latter finding suggests the possibility that a recessive gene that influences the development of leukemia may exist. Cases of concordance of reticulum cell sarcoma<sup>449,476</sup> or other types of lymphoma or leukemia<sup>457</sup> have been reported in twins, but the infrequency of these diseases in childhood leaves the sig-

nificance of the observations in doubt. Chromosome abnormalities were found to differ between a set of fraternal twins concordant for acute leukemia,<sup>466</sup> but were apparently the same in a set of identical twins concordant for AML in whom the defect was undetectable in nonleukemic cells.<sup>437</sup> Since identical twins have identical heredity it is tempting to ascribe their higher rate of concordant leukemia, as compared to that of fraternal twins, to inherited factors. Yet, it must be recognized that the in utero and postnatal environment is more likely to be the same in identical than in fraternal twins. Thus, twin data can be interpreted as supporting the concept that leukemia has an identifiable cause(s) rather than representing a completely random event in the population. They do little to identify the nature or timing of the cause.

Some familial instances of leukemia are ascribable to inheritance of a disease predisposing to leukemia (page 1462) such as ataxia telangiectasia<sup>472</sup> or Fanconi's aplastic anemia.<sup>411</sup> The possible relation of the inheritance of the Christchurch chromosome to CLL and of a Ph<sup>1</sup> chromosome to CML has been discussed (pages 1441-1444).

The finding of chromosome aberrations, including chromosome breaks and endoreduplication in healthy members of a family in which a child had partial D<sub>1</sub> trisomy and acute leukemia raised the question of some genetic factor influencing the chromosome pattern.<sup>479</sup>

With reference to genetic factors it is of some interest that the distribution of blood groups and transferrin types is quite similar in patients with leukemia as compared to the variations found in the general population.<sup>431</sup> Haptoglobin type 1/1 was found to be more frequent in patients with leukemia in general than in the general population,<sup>444</sup> although it was less frequent in patients with CLL.<sup>461</sup> Relatives of patients with CLL have not been found to have a high frequency of hypogammaglobulinemia,<sup>444</sup> in contrast to relatives of patients with Waldenström's macroglobulinemia.<sup>467</sup> Leukocyte HLA antigens were similar in patients with leukemia and in the gen-

eral population.<sup>442</sup> A higher frequency of certain HLA antigens has been reported in patients with HD<sup>418a,423</sup> but the significance of these observations is uncertain because of the differences in the reported findings.<sup>418a</sup> It is of some interest that genetic susceptibility to viral murine leukemia-lymphoma seems to be related to the frequency of certain murine transplantation antigens.<sup>266,448</sup>

## Ethnic Differences

A comparison of incidence in the white and non-white populations of the United States reveals that all forms of leukemia and lymphoma are more common in whites than in non-whites. These differences might be attributed to different standards of medical care were it not for the fact that myeloma appears to be more common in the non-white than in the white population (Table 46-2). Similarly, the apparent continuing rise in leukemia incidence in non-whites could be ascribed to improved medical care, but no such rise has been evident for HD (Table 46-2). These observations plus the lack of an early childhood peak of leukemia in non-whites<sup>421</sup> (Fig. 46-3) strongly suggest that ethnic differences play a role in the incidence of at least some of these diseases. Non-whites in the United States survey included Negro and Oriental populations.

The early peak of acute leukemia is less prominent in Japan than in the United States or in European Caucasian populations.<sup>40</sup> There are suggestions that lymphoblastic leukemia in Negro children is less responsive to therapy than that in Caucasians (Chapter 47). Observations also suggest that lymphoblastic leukemia may be more common in populations with European ancestry than in certain other populations.

Chronic lymphocytic leukemia is much less common in the Orient than in the United States. Comparison of mortality from leukemia of all varieties in the Japanese population, the white United States population, Japanese immigrants to the United States, and American-born Japanese indicates similar mortality rates in persons from ages 20 to

40.<sup>433</sup> Thereafter, all groups with Japanese ancestry show lower mortality rates than does the white population of the United States, even though Japanese living in the United States tend to have higher death rates than those living in Japan. Admitting that data for cell type are somewhat suspect, the difference appears to reflect a difference in the incidence of CLL primarily. Percentages of leukemia deaths listed as CLL were: Japan, 2.9; Japanese immigrants to the United States, 5.0; and United States whites, 31.5. These data could be interpreted as suggesting that the low frequency of CLL in Japanese is genetic rather than environmental, but certain cultural differences, such as diet, are not entirely erased by a change of residence. Lymphosarcoma in persons of all ages is less common in Japan than in the United States, but the lymphosarcoma mortality rates of Japanese immigrants to the United States more closely resemble those for the United States than for Japan.<sup>433</sup>

Some studies have provided evidence that there is an increased risk of leukemia in adults, but not children, of Russian Jewish heritage,<sup>430</sup> but others have failed to indicate a difference in leukemia rates in Jews versus non-Jews of similar country of origin.<sup>407</sup>

As greater attention is directed toward elucidating differences in the incidence of various diseases in ethnic groups and in different geographic areas, more definitive data are likely to be forthcoming.<sup>416</sup>

### Increased Frequency of Leukemia in Diseases Associated with Congenital Chromosome Abnormalities<sup>456</sup>

First reported in 1930,<sup>412</sup> the occurrence of leukemia in children with *Down's syndrome* (mongolism) has been documented by numerous case reports. In 1958, in a series of 677 children with acute leukemia, Stewart and coworkers<sup>470</sup> demonstrated that the number of those with Down's syndrome was 20

times greater than would be expected. Shortly thereafter, trisomy of chromosome 21 was demonstrated in children with Down's syndrome and was found to be a fairly constant defect in these subjects.<sup>456</sup> The leukemia in patients with Down's syndrome usually has been described as myeloblastic, but the frequency of lymphoblastic leukemia also has been reported to be increased.<sup>408,419,462</sup> A self-limited myeloblastic proliferation, indistinguishable from AML except for its disappearance without therapy, also has been noted in these children (Chapter 41),<sup>408,138</sup> as has polycythemia.<sup>475</sup> After leukemia develops the group G trisomy persists in the myeloid cells and the typical chromosome changes of acute leukemia (page 1443) often are superimposed.<sup>408a</sup> Of particular interest in this regard is a mongol in whom "congenital leukemia" was present; this remitted spontaneously, but then recurred. Chromosome abnormalities in addition to trisomy 21 were constantly present.<sup>438</sup> HD has developed in at least two patients with Down's syndrome<sup>151</sup> and there may be an increased frequency of other neoplasms as well.<sup>455</sup>

*Fanconi's anemia* appears to be associated with an abnormally high frequency of leukemia.<sup>420</sup> Chromosome breaks and gaps have been noted in high frequency in cells from patients with Fanconi's anemia, although there are no specific identifying defects and a diploid chromosome number has been present.<sup>474</sup> An increased frequency of acute leukemia also has been observed in such children.<sup>474</sup> Similar chromosome changes have been observed in *Bloom's syndrome*, which likewise is associated with increased frequency of leukemia.<sup>156</sup> The familial occurrence of the Ph<sup>1</sup> defect and its relation to CML have been discussed (page 1441), as has the possible relation of inherited G group abnormalities to familial cases of CLL (page 1444). A balanced group C-G translocation, found in three members of a family, was associated with ALL in an affected member whose mother, chromosome type unknown, also had ALL.<sup>120</sup> Patients with Klinefelter's syndrome who developed acute leukemia or lymphoma have been described.<sup>450</sup>

The significance of these chromosome abnormalities with respect to the development of leukemia is unknown.

## Association with Other Diseases

A variety of case reports as well as some patient surveys suggest that AML occurs with greater frequency in patients with paroxysmal nocturnal hemoglobinuria (PNH) (Chapter 29),<sup>413,439,440</sup> pernicious anemia (Chapter 15),<sup>410</sup> or aplastic anemia (Chapter 56), than in the general population and that AML and MM develop with some frequency in patients with sideroblastic anemia.<sup>415</sup> CML has also developed in a patient with PNH.<sup>472a</sup> All of these diseases are associated with abnormalities of cellular proliferation and one might postulate that in any disease characterized by changed proliferation there is an increased chance of producing a "leukemic clone." The absence of any known association of leukemia with disorders in which there is increased proliferation such as sickle cell anemia, thalassemia, or hereditary spherocytosis or in persons frequently donating blood weakens this interpretation. No association between hemolytic disease of the newborn (Chapter 27) and leukemia could be established in a retrospective survey.<sup>321</sup> Lymphoma may follow hyperthyroidism more often than would be expected.<sup>473</sup>

The frequency with which leukemia or lymphoma develops in association with congenital immune deficiency diseases<sup>422,426,429</sup> (Chapter 44) or in immunosuppressed patients<sup>163</sup> suggests that a fully functioning immune system provides some protection against these diseases.<sup>79</sup> Immune suppression is clearly a factor in inducing neoplasms in animals.<sup>417</sup> Alternatively, one could postulate that if intact portions of the immune system are overstimulated in persons with a congenital deficiency disease, the increased frequency of leukemia and lymphoma might merely reflect an increased probability of producing an abnormal clone of lymphoid cells.

The diffuse connective tissue disorders such

as rheumatoid arthritis, dermatomyositis, and lupus erythematosus appear to be associated with lymphocytic leukemia and lymphoma more often than can be accounted for by chance or in relation to therapy. Miller<sup>454</sup> reported observations in 14 cases patients and surveyed a large group of patients with cancer or lymphoid neoplasms for the presence of connective tissue disease. Such diseases were found in 1.9% of patients with lymphoid neoplasms, but in only 0.6% of patients with solid tumors of the breast, gastrointestinal tract and other tissues. Other surveys of their frequency in association with lymphoma range from 0.4<sup>409</sup> to 2.2%.<sup>404</sup> The incidence of these connective tissue diseases in the general population is estimated at 0.4%.<sup>451</sup> Lea and associates<sup>445</sup> surveyed a population of patients with leukemia and lymphoma for other diseases and compared them to a control population. Fractures, other injuries, and chronic sepsis were equally frequent in the populations studied, but rheumatic diseases were two to four times as frequent in patients with leukemia (type not specified), non-Hodgkin's lymphoma, and Hodgkin's disease than in the control population. The frequency of lymphoma also may be increased in Sjogren's syndrome, a disorder often associated with rheumatoid arthritis.<sup>472</sup>

There appears to be a negative association of leukemia with atherosclerosis<sup>460</sup> and essential hypertension.<sup>477</sup> Single case reports of leukemia developing in persons with conditions such as Gaucher's disease<sup>427</sup> and congenital agranulocytosis<sup>428</sup> are interesting, but of unknown significance.

- Course, Complications, and Cause of Death
- Survival
- Therapy
  - General Principles
  - Therapy of ALL
  - Therapy of AML

THE acute leukemias are characterized by an increase in very immature leukocytes, usually myeloblasts or lymphoblasts, in the blood and/or marrow (Plates XVIII and XIX). Unless the subjects are treated, these diseases are fatal within a brief time. The lymphoblastic and myeloblastic forms differ in response to therapy, age distribution, and in various other ways, but there is considerable similarity in their modes of presentation

and complications. Acute leukemia can occur in persons of any age, from in utero (page 1476) even to age 100.<sup>19</sup> The history, possible etiologic factors, age and sex distribution, and the relation to other diseases have been discussed (Chapter 46).

### Acute Lymphoblastic Leukemia (ALL)

Although acute lymphoblastic leukemia can occur in individuals of any age, it is predominantly a disease of children. Typically, the leukemic cell is quite immature. It has fine nuclear chromatin and nucleoli. In the lymphoblast there is slight clumping of the chromatin, allowing the cell to be distinguished from a myeloblast (page 1478). Smaller, but still immature-appearing lymphocytic cells also are usually present. Rarely, especially in children, the cells appear rather mature but the clinical manifestations of ALL and chronic lymphocytic leukemia (Chapter 49) are so different that these two forms of leukemia would hardly be confused. (see ref 19). The only ALL variant of note is *lymphosarcoma cell leukemia* (leukosarcoma, lympholeukosarcoma) (Chapter 51). Although there may be morphologic<sup>148</sup> and perhaps biochemical<sup>163</sup> differences between this leukemia and typical ALL, in many instances the cells in either disease are morphologically indistinguishable from those in the other. We reserve the term "lymphosarcoma

cell leukemia" to designate cases diagnosed as lymphosarcoma (Chapter 51) at a time when the marrow and blood were not involved but which later became leukemic. In general, once conversion to a lymphoblastic picture occurs, the course is similar to that in other patients with ALL,<sup>148,167</sup> although the therapeutic response may not be as good as that in the patient in whom the ALL had a typical beginning. *Stem cell leukemia*, or "undifferentiated acute leukemia," is a term used by some investigators as a synonym for ALL.<sup>188</sup> Others have suggested that the survival rate may be lower in patients with "stem cell" than in those with "lymphoblastic" leukemia and claim that different clinical types of lymphoblastic leukemia can be distinguished morphologically.<sup>120</sup>

## Acute Myeloblastic Leukemia (AML)

The term "acute myeloblastic leukemia" (AML) will be used here to include a group of morphologically distinguishable syndromes (Table 47-1) which are similar in clinical presentation, course, and response to therapy. As judged by average survival time after the diagnosis has been made or by response to therapy, AML is probably the most malignant of all neoplastic diseases.

The exact frequency of the various subtypes of AML depends on definition since, in most instances, a completely "pure" picture is lacking.<sup>19,145</sup> Thus, in most patients with myeloblastic leukemia, in addition to the predominating myeloblasts, a few cells with lacy chromatin and folded nuclei, "monocytoid" myeloblasts, may be observed and a few "blasts" will have peroxidase-positive granules in the cytoplasm. Similarly, occasional proerythroblasts with megaloblastic features may be observed in the bone marrow.

### Morphologic Differences of AML Variants

The subtypes of AML listed in Table 47-1 are recognized by the characteristics of the

**Table 47-1. Diseases Included Under the General Term, Acute Myeloblastic Leukemia**

<i>Term</i>	<i>Characteristic Cell</i>
Acute myeloblastic leukemia (AML) ✓	Myeloblasts
Acute myelomonoblastic leukemia (Naegeli) (AMML)	Myeloblasts with some monocytic characteristics
Acute monoblastic leukemia (Schilling) (AMoL)	Immature monocytes
Acute promyelocytic leukemia (APML)	Promyelocytes
D <sub>1</sub> Guglielmo's syndromes	Myeloblasts—proerythroblasts
D <sub>2</sub> Guglielmo's disease	Proerythroblasts

abnormal cells. These are described below and are illustrated in Plates XVIII and XIX, pages 1474 and 1478.

**MYELOBLASTIC LEUKEMIA.** The predominant abnormal cells in blood and marrow are myeloblasts with round nuclei, fine nuclear chromatin, scanty cytoplasm, round and regular cytoplasmic borders, and no cytoplasmic granules. These cells are peroxidase negative.

**MYELOMONOBLASTIC LEUKEMIA (NÆGELI TYPE MONOCYTIC LEUKEMIA).** The most common abnormal cell in the blood and marrow has features of myeloblasts and of monocytes. The nucleus of many of the cells is folded and nuclear chromatin is fine but reticular. There often is more abundant cytoplasm than in myeloblasts and the cytoplasmic border may be irregular and may show pseudopod formation. Granules may or may not be present in the cytoplasm. In general, the cells in the blood tend to appear more monocytic than do those in the marrow.

**MONOBLASTIC LEUKEMIA (SCHILLING TYPE MONOCYTIC LEUKEMIA).** Virtually all abnormal cells have monocytic nuclear and cytoplasmic characteristics. The cells often are large and have serrated borders. Rarely, marked phagocytosis is evident as indicated by the presence of engulfed red corpuscles in the cytoplasm. The differences in morpho-

Fig. 47-1 Swollen and spongy gums in a patient with acute myelomonoblastic leukemia

logic appearance of "monoblasts" and myeloblasts as noted by light microscopy are even more evident on electron microscopy.<sup>61</sup> The monoblast nuclei exhibit extreme irregularity and are folded, while myeloblast nuclei are regular and round. Bridges between chromatin strands and "blebs" of the nuclear chromatin may explain the reticular, granulated appearance of the nuclear chromatin of monoblasts as seen by light microscopy. The Golgi apparatus of monoblasts is more prominent and cytoplasmic mitochondria, granules, vesicles, vacuoles, and pseudopods are more apparent in monoblasts than in myeloblasts or in myelomonoblasts.

**PROMYELOCYTIC LEUKEMIA.** More than half of the immature cells have cytoplasmic granulation which is peroxidase positive. The granules may be normal in appearance or abnormally large or oval, rather than round. Eosinophilic, basophilic, or both forms of granules may be present.<sup>88,152</sup> The nucleus may appear more immature than in the normal promyelocyte with very fine chromatin and prominent nucleoli.

**DI GUGLIELMO'S SYNDROMES (ACUTE AND CHRONIC ERYTHREMIC MYELOSIS, ERYTHROLEUKEMIA, see below).** In acute erythremic myelosis proerythroblasts predominate and there is little or no increase in myeloblasts. In chronic erythremic myelosis the erythroblasts are somewhat more mature. In eryth-

roleukemia there is also a marked increase in proerythroblasts but myeloblasts (or myelomonoblasts or promyelocytes) are increased as well. The proerythroblasts of Di Guglielmo's syndrome may resemble megaloblasts and manifest other morphologic abnormalities such as binucleation. In contrast to the negative PAS staining of other forms of leukemic myeloblasts and of normal proerythroblasts, the myeloblasts and proerythroblasts of Di Guglielmo's syndrome are PAS positive<sup>137</sup> (Plate XXII). Giant granules in eosinophils also have been described.<sup>58</sup>

### Clinical Differences between Morphologic Variants

Features other than morphologic differences whereby the varieties of AML differ are few.<sup>19,20</sup>

**MYELOMONOBLASTIC AND MONOBLASTIC LEUKEMIA.** In myelomonoblastic or monoblastic leukemia, gum infiltration (Fig. 47-1) is a common feature; this is less frequent in other types of AL.<sup>19</sup> Increased frequency of skin infiltration in these varieties of AML has been claimed,<sup>59</sup> but this could not be confirmed in our series.<sup>19</sup> Some immature, leukemic monocytes migrate into inflammatory exudates while myeloblasts do not<sup>147</sup>; this migratory capability may explain the gum infiltration.<sup>116</sup> Whether monoblastic leukemia is a distinct entity or represents merely one end of the morphologic spectrum of AML is unknown at present. Much of the literature on this subject was written on the assumption that the "Nageli" type arose from the myeloblast while the "Schilling" variety arose from a different cell system. We now know that the myeloblast and monocyte have a common stem cell (Chapters 2 and 6).

**PROMYELOCYTIC LEUKEMIA.** In promyelocytic leukemia, particularly when large, abnormal-appearing granules are frequent in the cells, hypofibrinogenemic bleeding (Chapter 54) is more common than in other types of AML.<sup>19,43</sup> The suggestion that this may be a more severe disorder than other forms of AML<sup>11</sup> was not substantiated by analysis of our series of patients.<sup>20,43</sup>

**DI GUGLIELMO'S SYNDROME.** The distinguished Italian hematologist, Di Guglielmo, first called attention to a condition characterized by neoplastic hyperplasia of both erythroblastic and leukoblastic tissues, which he called erythroleukemia. Shortly afterwards (1923), he applied the term acute erythremic myelosis to a disorder characterized by a generalized proliferation of the erythropoietic cells of the bone marrow, analogous to the leukocytic proliferation in leukemia.<sup>44</sup> He suggested that this is a primary and specific disease, an autonomous pathologic entity. The blood contains erythroblasts in all stages of maturation, but the most immature forms are found in disproportionately large numbers. Atypical forms and erythroblasts with multilobed nuclei and with altered nucleocytoplasmic ratios also are found. Reticulocytes are not usually increased in number. Increased levels of fetal hemoglobin may be found.<sup>34</sup> There is slight leukopenia, and occasional myelocytes and metamyelocytes, as well as reticuloendothelial cells, may be present in the blood smear. Platelets are decreased in number, often greatly. In contrast to the reduced proportion of erythropoietic elements characteristic of leukemia, these form the major part of the bone marrow cells, and basophilic forms predominate. At autopsy, infiltrations of primitive erythroblasts and reticuloendothelial cells are found not only in the hematopoietic organs but also in the kidneys, adrenal glands, and other tissues.

Subsequently Di Guglielmo called attention to a similar but more chronic disorder, chronic erythremic myelosis, also marked by the presence in the bone marrow of numerous erythroblasts but these were mainly the more mature forms. Hemorrhagic manifestations are less prominent. There may not be leukopenia and there is only moderate thrombocytopenia, but reticulocytes are usually increased, sometimes strikingly.

Acute erythemic myelosis and erythroleukemia follow a clinical course that cannot be distinguished from that of AML except for the excessive number of erythroblasts. These conditions respond to therapy as does AML.<sup>19</sup> As the name implies, chronic erythremic myelosis follows a more indolent

course and because most of the subjects eventually die of an AML-like disease<sup>41,100,172</sup> it may be best described as a form of "preleukemia" (page 1476). The nature of the anemia in Di Guglielmo's syndrome is discussed in Chapter 54 (page 1667). Distinguishing Di Guglielmo's syndrome from sideroblastic anemia and other idiopathic anemias with ineffective erythropoiesis (Chapter 18) may be difficult.<sup>172</sup> It has been suggested that whether or not idiopathic forms of anemia will eventuate in AML can be predicted by the normal appearance of the red cell precursors and normal platelet counts in the anemias that will not eventuate in AML in contrast to the presence of defects in heme synthesis in those that will.<sup>45</sup> Polycythemia vera has been reported to have terminated in acute erythremic myelosis.<sup>41</sup>

## Other Forms of Acute Leukemia

### Acute Eosinophilic Leukemia

In addition to acute leukemia in which eosinophilic promyelocytes are the predominant cells and the leukemia that might be considered chronic eosinophilic leukemia (Chapter 48) (page 1513),<sup>88,152</sup> there is another syndrome that may be termed "eosinophilic leukemia." In 1919, Griffin<sup>73</sup> described a patient with hepatosplenomegaly, lymphadenopathy, and shifting pulmonary infiltrates who died with severe congestive heart failure. This patient had as many as  $170 \times 10^9$  eosinophils/l of blood, most of which were segmented and abnormally large but had sparse granulation. He was anemic and, at postmortem examination, endocarditis and eosinophilic infiltration of organs such as the spleen and lymph nodes were noted. Numerous reports of similar cases have appeared under diverse headings such as "eosinophilic leukemia,"<sup>9,10,78</sup> "disseminated eosinophilic collagen disease,"<sup>160</sup> and "Löfller's endocarditis parietalis fibroplastica with eosinophilia."<sup>182</sup> The similarity of the course and complications of a number of the cases suggests that the disease is a distinct entity and whether it should be called leukemia or given

some other name seems immaterial in our present state of ignorance regarding the cause of the eosinophilia. Anemia, neutropenia, and thrombocytopenia may or may not accompany the eosinophilia. Pulmonary symptoms associated with shifting infiltrates, sterile endocarditis with congestive heart failure, and migratory thrombophlebitis with embolization characterize the course of the disease and constitute the usual causes of death. A variety of standards for a diagnosis of true "leukemia" have been proposed<sup>7,78,160</sup> including a terminal blastic stage.<sup>162</sup> Blastic transformation of the disease has been noted by us and by others,<sup>162</sup> suggesting that the designation of leukemia is appropriate in at least some patients. However, marked eosinophilia as such must not be interpreted automatically as eosinophilic leukemia. Unless there are ancillary findings suggesting that the patient will follow the course described in acute or chronic (Chapter 48) eosinophilic leukemia it is probably unwise to use this term. Such patients may prove to have periarthritis, carcinoma, Hodgkin's disease, or a variety of other diseases associated with eosinophilia (Chapter 41), or eosinophilia may persist for many years and remain unexplained.

### Mast Cell Leukemia

In the congenital disease, "urticaria pigmentosa" there is an associated increase in concentration of mast cells in the ultraviolet-sensitive skin of the patients. An acquired disease in adults has similar characteristics. In some patients with either congenital or acquired disease, increased mast cells also are found in the liver and other organs; in such cases the designation "systemic mastocytosis" has been applied.<sup>30</sup> In extreme cases of systemic mastocytosis, large numbers of mast cells are found in the patient's blood and the condition may prove fatal, leading some authors to designate it as "mast cell leukemia."<sup>67</sup> In the sense that the mast cell accumulation does not seem to represent a response to an identified stimulus, the disease can be considered a tumor and, when the number of mast cells in the blood is high,

leukemia. Since the relationship of the mast cell to basophils or other myeloid elements is poorly defined (Chapter 2), the syndrome cannot be meaningfully related to hematopoietic tumors at the present time. A chronic form of leukemia may be associated with a marked increase in basophils (Chapter 48), and, as noted (page 1474), in promyelocytic leukemia prominent basophilic granules may be present in the immature cells.

### Congenital Leukemia

More than 100 cases of congenital leukemia in which evidence of the disease was present within the first week of life have been reported.<sup>19,25,71,15,83,166</sup> Most of these newborn infants as well as most of those developing leukemia during the first year of life have suffered from AML rather than ALL, in contrast to the usual findings in children developing leukemia after the first year (page 1478). Congenital leukemia has two features that are uncommon in older patients with AML—the patients frequently are not anemic and the majority have leukemic infiltration of the skin. *Leukemoid reactions* of unknown cause closely mimicking AML also have been reported in newborns and must be distinguished from true AML.<sup>4,51,126</sup> As with AML manifested at any age, in congenital leukemia the survival usually is of short duration although spontaneous<sup>36</sup> and chemotherapy-induced<sup>136</sup> remissions have been reported. One mother delivered at least two and probably four children with congenital leukemia.<sup>29</sup> Since there was no other family history of leukemia and chromosome studies showed no abnormality in either parent, some in utero event leading to such a remarkable occurrence might be postulated. However, an abnormal uterine environment could not account for the observation that of two pairs of twins—one fraternal<sup>89</sup> and one identical<sup>180</sup>—only one of each pair was affected by congenital leukemia.

### Preleukemia<sup>17</sup>

Diseases which may terminate in AML were discussed in Chapter 46. In addition, a

hematologic defect, most often anemia, may be noted in patients in whom no diagnosis can be established after careful study. Some months or even years later a fairly typical picture of AML evolves. "Preleukemia"<sup>17</sup> seems a reasonable term for designation of this condition and has been applied when the diagnosis of AML may be suspected but cannot be made with any confidence. The term "smoldering leukemia"<sup>133</sup> also has been used to denote this condition but it implies a predicted behavior for the disease and the leukemia may not "smolder" once it becomes apparent.<sup>19</sup> Certain cases described as chronic monocytic leukemia<sup>157</sup> also can fit the designation of preleukemia as used here. Most patients with preleukemia have been elderly, but this syndrome can occur in persons of any age, including infants.<sup>47</sup> Most patients with preleukemia have developed AML, but ALL has also been reported to follow preleukemia in children.<sup>123</sup> Approximately 15% of our patients with AML have undergone a preleukemic phase. Except for the diagnostic enigma when these patients were first examined, the eventual symptoms and course did not differ significantly from those experienced by other patients with AML. Survival from the time of diagnosis to death was also similar to that of other patients with AML.<sup>19</sup>

The most consistent abnormality identified in patients who prove to have preleukemia is the presence of anemia.<sup>16,17,19,122</sup> The anemia usually is normocytic and normochromic and is accompanied by a normal or decreased reticulocyte count. Sometimes it is microcytic and hypochromic, and in such instances ringed sideroblasts (Chapter 47) often are demonstrable in the bone marrow. In other cases a hypochromic cell with basophilic stippling is seen beside normocytic or macrocytic normochromic red cells. In the presence of macrocytic anemia and cells in the bone marrow which suggest megaloblasts, a diagnosis of Di Guglielmo's syndrome has often been entertained when various causes of megaloblastosis (Chapter 14) have been ruled out. Blood neutrophils may be normal or decreased in number and the number of platelets may be normal, decreased, or even increased. The percentage of myeloblasts in

the marrow may be normal or slightly increased. There is no exact percentage of myeloblasts that "establishes" a diagnosis of AML, but we would be very reluctant to make a firm diagnosis if fewer than 10% were present. The spleen and/or liver may be palpably enlarged, but sternal tenderness and lymphadenopathy are unusual in preleukemia. Although no test is available to determine what patients with unexplained anemia or with a reduction in two or all the formed elements of the blood ("bi-" or pancytopenia) will develop AML, certain findings suggest this diagnosis. Thus, the presence of an aneuploid cell line in direct chromosome preparations from bone marrow is strong evidence for leukemia<sup>127</sup> (Chapter 46). Many patients with AML have an abnormally low leukocyte alkaline phosphatase; such a finding suggests this diagnosis or paroxysmal nocturnal hemoglobinuria (Chapter 46). *In vitro* culture, in semisolid media, of marrow from some preleukemic patients may be helpful.<sup>72</sup> No growth may appear or abnormally small colonies may form. Marrow cells from such patients may also fail to mature in liquid culture.<sup>69a</sup>

### Miscellaneous Forms

Chloroma is a term applied to localized tumors of granulocytic tissue, especially those involving the orbit.<sup>49,143</sup> The name is derived from the observation that the cut surface of such tumors transiently turns green when exposed to light, a phenomenon that probably reflects the myeloperoxidase content of the cellular lysosomes.<sup>149</sup> On rare occasions, chloromas may appear at a time when the leukemia is in an early stage, but no convincing reports<sup>179</sup> of cure of an isolated chloroma have appeared since 1927.<sup>111</sup> Certain authors<sup>130,139</sup> have considered the leukemia associated with chloromas to differ from other forms of AML.

Still other categories of AML have been suggested<sup>120</sup>; *megakaryocytic leukemia*<sup>3</sup> is discussed in Chapter 48. Occasionally myeloblasts are smaller than normal; in such cases the term *micromyeloblastic leukemia* has been applied. An occasional patient maintains

a normal or even increased number of apparently mature segmented neutrophils despite the increase in blasts in the marrow, a condition which has been designated acute neutrophilic leukemia.<sup>46</sup> The term *subacute* has been applied in two situations—for AML in patients who have lived for more than six months and in patients in whom some neutrophilic maturation was present.<sup>19</sup>

The malignant *reticulosos* (Chapter 51) have some features suggesting acute leukemia.

## Distinguishing ALL from AML

### Age and Sex Distributions

The age distributions of ALL and AML differ quite markedly (Fig. 47-2). More than 80% of cases of leukemia in children were lymphoblastic in origin and in certain other studies.<sup>19,42,65,118</sup> However, 32% of patients seen at the Children's Cancer Foundation in Boston were considered to have AML,<sup>60</sup> and AML was thought to occur almost as frequently as ALL in children in one British series.<sup>140</sup> In persons in the teens and early twenties, ALL and AML occur with about equal frequency, but, as age progresses, AML becomes increasingly predominant whereas ALL is a relatively rare disease in persons 45 years of age or older. Sex ratios are approximately 3 males to 2 females for both conditions (Chapter 46).

Morphology (Plates XVIII and XIX, pages 1474 and 1478)

Although there are certain symptoms, signs, and laboratory features which in general are more common in ALL than in AML, in individual cases the differentiation depends on examination of the immature cells.<sup>19</sup> The skilled morphologist usually can make the

Fig. 47-2. Relative frequencies of ALL and AML as they vary with age in 500 patients; two series combined.<sup>19,65</sup>

differentiation with some certainty by examining well-made blood or bone marrow smears treated with Romanowsky stains. When slides properly prepared with Romanowsky's stain have been subjected to blind review by a panel of expert morphologists, general agreement as to type has varied from 75 to 95%.<sup>80,112,178</sup> (see also ref. 19). The diagnosis of AML is obvious when, together with "blasts" containing nucleoli, cells are present with evident granules, which are confirmed as peroxidase positive, or cells with monocytoid features are found, or when abnormal erythroblasts suggesting Di Guglielmo's syndrome are evident. Auer rods (Chapter 46) are easily demonstrable in "blasts" in approximately 10% of patients with AML<sup>140</sup> and can be found in an even higher percentage when a careful search is made.<sup>19</sup> In contrast, in many ALL patients lymphoblastic maturation has proceeded to the

point that the nuclear chromatin is easily seen as being more dense than in myeloblasts and may be identified as lymphocytic. However, in other patients, certainly less than half, the predominant cell is a blast having few obvious signs of cytoplasmic or nuclear maturation. Adding to the difficulty, occasional promyelocytes or myelocytes may be observed in the blood of patients with ALL, especially in those with high leukocyte counts.<sup>19,125</sup> Thus, identification of blasts "by the company they keep" is not wholly reliable and may account for some reports of "mixed" leukemia.<sup>37</sup> In this circumstance, more subtle morphologic features must be looked for. The nuclear chromatin of lymphoblasts is slightly but visibly clumped in an irregular pattern, while that of the myeloblast is uniformly fine, finely granular, or lacelike in appearance. The nuclear membrane is of irregular thickness in ALL and thin and of uniform thickness in AML, a feature best appreciated in living cells examined by means of phase microscopy. There tends to be a larger number of nucleoli in myeloblasts than in lymphoblasts (Chapter 6).

Stains for peroxidase, periodic acid-Schiff staining, and Sudan Black B staining will sometimes help to distinguish AML from ALL.<sup>80,81</sup> However, these detect maturing characteristics of cytoplasm, granules in AML, or glycogen in ALL and usually confirm what is seen in Romanowsky stained smears. They are of limited help in the difficult case in which the cells are uniformly immature. Leukocyte alkaline phosphatase (LAP) stains are of some help if enough mature neutrophils are available to permit a meaningful test. The LAP score tends to be high in ALL and low in AML.<sup>81</sup> Finding elevated serum or urinary muramidase often identifies acute monoblastic or myelomonoblastic leukemia,<sup>33,153</sup> but such cases usually are readily recognized on morphologic study. A variety of other tests of cellular function or chemistry may help to distinguish ALL from AML, such as motility (Chapter 6), arylsulphatase staining,<sup>108,121</sup> and esterase staining with naphthyl acetate.<sup>144</sup> However, these tests are not generally available and have not been proven to be exact enough to justify their

routine use. Serum B<sub>12</sub> levels may be elevated in AML but are usually normal in ALL.<sup>8</sup>

Study of chromosome changes in direct marrow or blood preparations may be helpful. When aneuploidy is present the line is almost invariably hyperdiploid in ALL, whereas there may be either hyper- or hypoploidy in AML (Chapter 46).

## Modes of Presentation<sup>19,140,159</sup>

### Symptoms

The most common complaint at the time of diagnosis is that of *fatigue* or *malaise*, or of a poorly defined sense of ill health (Table 47-2). In the average patient the complaint has been present for several months before the diagnosis is made. The symptomatic period preceding diagnosis tends to be longer in AML than in ALL patients, perhaps reflecting the frequency of "preleukemia" (page 1477) in the former. The presence and severity of fatigue bear some relation to the presence and severity of anemia.<sup>19</sup> Fatigue is the primary complaint of about half of the patients and is part of the presenting picture in most.

*Fever*, with or without demonstrable infection or other symptoms of infection, is the primary presenting complaint in 15 to 20% of patients. Fever has been noted by approximately half of the patients with AML by the time the diagnosis has been made and is even more common in patients with ALL. A documented infection is less common than a history of fever. Complaints of sweating, usually night sweats, are rare in the absence of fever. As noted in Chapter 54, severe neutropenia usually is present in the infected patient, but there are no demonstrable laboratory features that correlate with fever without infection.<sup>18</sup>

Approximately 10% of patients consult a physician because of easy bruising, petechiae, nosebleed, or other hemorrhagic phenomena (Figs. 47-3 and 47-4); half have noted such difficulties by the time of diagnosis. The presence and severity of complaints of hemorrhagic phenomena correlate well with the severity of thrombocytopenia (Chapter 54).

Table 47-2. Symptoms and Signs at Time of Diagnosis of Acute Leukemia

	ALL (178 Patients) (% of Patients)	AML (144 Patients) (% of Patients)
Symptoms		
Fatigue	92	86
Fever without infection	71	48
Infection	17	26
Purpura	51	30
Other hemorrhage	27	34
Bone or joint pain	79	20
Weight loss	66	47
Abnormal masses	62	11
Physical findings		
Splenomegaly	86✓	60
Hepatomegaly	✓74	54
Lymphadenopathy	76	47
Sternal tenderness	69	65
Petechias and/or ecchymoses	50	46
Fundic hemorrhage	14	16

*Weight loss* is noted by about one half the patients but is rarely severe and thus is rarely the chief complaint. Pain in the bones or joints occasionally is severe enough to bring the patient to the physician and is more common in ALL than in AML patients. Head-

ache or cough without apparent pulmonary infection is experienced with some frequency but is rarely a primary feature.

The patient with AML rarely notes enlarged nodes or abdominal masses, but the ALL patient does so more frequently. Since

Fig 47-3 Fundus oculi in a patient with acute leukemia. There are numerous flame-shaped hemorrhages as well as small and large irregularly round hemorrhages. Clear centers are visible in some of the hemorrhages. The caliber of the veins is greatly increased, that of the arteries decreased. (Courtesy of Dr. Alan C. Woods)

Fig 47-4 Fundus oculi in a patient with acute lymphoblastic leukemia. The outlines of the optic disk are blurred. There are striae and subhyaloid hemorrhages. The caliber of the veins is increased, that of the arteries decreased. The vessels are tortuous and many are marked by whitish streaks. The retina has a veil-like appearance. (Courtesy of Dr. Alan C. Woods)

virtually any organ can be involved by leukemic infiltration or by hemorrhage or infection, a variety of unusual presenting complaints such as seizures, loss of vision, and gum hypertrophy are occasionally noted.

#### Physical and Radiologic Findings at Time of Diagnosis (Table 47-2)<sup>19</sup>

The primary physical findings relate to anemia (*pallor*, tachycardia, cardiac murmurs presumably of hemic origin), thrombocytopenia (petechiae and ecchymoses or other hemorrhages), neutropenia (infection), or leukemic infiltration (splenomegaly, hepatomegaly, lymphadenopathy, sternal tenderness).

Slightly more than half the patients with AML have *splenomegaly* and/or *hepatomegaly* at the time of diagnosis. The spleen, if palpable, usually is less than 5 cm below the costal margin. It is more frequently palpable and tends to be larger in patients with ALL than in AML.<sup>12,19</sup> *Lymph nodes* may be infiltrated and enlarged in AML patients, but are less prominent than in those with ALL.<sup>12,19</sup> Hilar lymph node enlargement or thymic enlargement is found on chest x ray in a small percentage of patients with ALL, but is unusual in those with AML. Parenchymal pulmonary infiltration is uncommon in acute leukemia (Chapter 54). Hepatomegaly rarely is symptomatic; neither is splenomegaly, unless a splenic infarct occurs. The course of a splenic infarct, recognized by left upper-quadrant pain accentuated by respiration and accompanied by friction rub, is usually uneventful (Chapter 54). Fewer than 10% of patients suffer recognized splenic infarcts during the course of disease.

*Sternal tenderness* is demonstrable in approximately two thirds of the patients and thus is a fairly reliable sign although it is not quite as common as it is in CML (Chapter 48). The usefulness of sternal tenderness as a diagnostic sign has been questioned since "pain threshold" as measured by applying graded pressure to one spot on the sternum was not "reliably decreased" in leukemia.<sup>121</sup> Sternal tenderness, however, usually does not

involve the entire sternum. Rather, as firm pressure is sequentially and systematically applied from top to bottom of the sternum, a small area, most commonly in the mid-body, is found which is quite tender. Normal persons may say that such pressure is "painful" if questioned, but in them spontaneous complaints or withdrawal with wincing during the examination are not usually elicited. Sternal tenderness also can be found in other patients such as those with severe hemolytic anemia and very hyperplastic bone marrow, and thus is not limited to leukemia patients.

Just as complaints of bone pain are more common in ALL than in AML patients, so are *bone lesions* more commonly demonstrable by x ray in ALL than in AML patients<sup>12,69,176</sup> (Chapter 54). The *skin* is noticeably infiltrated in approximately 10% of leukemia patients. This usually takes the form of a diffuse, plaque-like, violaceous lesion (Chapter 54). Gum infiltration, as previously noted, is suggestive of myelomonoblastic leukemia (Fig. 47-1). Physical evidence of disease at the time of diagnosis is lacking in a small but significant number of patients with AML but this is most unusual in ALL patients.

*Meningeal infiltration* may be present at the time of diagnosis<sup>93</sup> and lumbar puncture reveals leukemic cells in the CSF in some asymptomatic patients (Chapter 54). The frequency and significance of all of the above complications are discussed further in Chapter 54.

#### Laboratory Findings

*Blood findings* at the time of diagnosis are presented in Table 47-3.

The *leukocyte count* is elevated in slightly more than half of the patients. Even when the count is normal or low, blasts usually are demonstrable in the blood smear ("sub-leukemic leukemia"). More than  $100 \times 10^9$  leukocytes/l are present in fewer than 20% of patients, although more than  $1,000 \times 10^9/l$  may be found rarely. Leukocyte counts generally mirror blast levels since neutro-

Table 47-3. The Blood at Diagnosis of Acute Leukemia

	ALL (178 Patients) (%)	AML (144 Patients) (%)
Total leukocytes (per liter)		
$< 5.0 \times 10^9$	25	29
$5.0-10.0 \times 10^9$	15	15

penia is often present. In general, there is little correlation between the number of blasts in the blood and the size of the spleen, or between blast levels and other manifestations of infiltration.<sup>19,101,125</sup>

The frequency of *aleukemic leukemia*, which we define as no blasts seen on blood smear, depends on the intensity of the search. If routine differential counting is employed, no blasts will be noted in approximately 5% of patients, but scanning of smears or examination of buffy-coat preparations reduces this figure. Aleukemic patients usually are leukopenic, thus providing a clue to a leukocyte abnormality. ✓

*Anemia* is an important finding and often is quite severe. It is usually normocytic and normochromic, although in AML with *Di Guglielmo* features it may be macrocytic. Nucleated red cells may be noted in the blood and are more common in AML than in ALL patients (Table 47-3). Reticulocytopenia usually is present (Table 47-3), reflecting decreased cell production (Chapter 54).

*Thrombocytopenia* is present in most instances and is frequently pronounced at diagnosis. On very rare occasions thrombocytosis may be present.<sup>5</sup> Large bizarre platelets similar to those seen in CML (Chapter 48) or polycythemia vera (Chapter 30) may be observed in AML.

*Serum uric acid* levels are elevated in approximately half the patients, and urinary uric acid excretion is increased in almost all.<sup>87</sup> Symptomatic gout is quite rare<sup>181</sup> (Chapter 54). Uric acid nephropathy (Chapter 54) occasionally is observed in untreated patients and constitutes a significant hazard in patients receiving treatment unless appropriate preventive measures are taken<sup>103</sup> (Chapter 54). Hypercalcemia has been observed but is uncommon (Chapter 54). *Serum protein*<sup>53</sup> changes are somewhat different in ALL than in AML patients in that diffuse hypergammaglobulinemia is common in those with AML whereas gamma globulin usually is normal in those with ALL. Serum albumin is normal in most patients at the time of diagnosis, but declines as disease advances. Elevation of beta globulins is common and increased alpha globulins often reflect the presence of fever or infection (Chapter 54). On rare occasions, monoclonal protein spikes may be present.<sup>161</sup> Although decreased serum gamma globulin is unusual, anergy may be present.<sup>85</sup>

*Bone marrow* biopsy most commonly reveals a hypercellular marrow, but may reveal hypocellular or even (very rarely) necrotic parenchyma.<sup>24</sup> Thus it is to be anticipated that marrow aspiration usually will yield adequate material for examination and for diagnosis. In most patients the predominant cell in marrow smears is a blast. However, in some patients, particularly those with AML, replacement by blasts is only moderate and numerous normally appearing marrow cells may be present. Diagnostic marrow examination is unnecessary if numerous blasts are present in the blood. Marrow examination may be quite important in distinguishing between active disease and drug toxicity as a cause of cytopenia if no blasts are demonstrable on the blood smear. Because blasts

invariably disappear from the blood before disappearing from the marrow, no advantage is gained by study of the marrow in evaluating the course of therapy as long as blasts are present in the blood.

## Differential Diagnosis

There are but a few potentially benign conditions that mimic acute leukemia. Most diagnostic difficulties or delayed diagnoses represent failure to consider the diagnosis or to make adequate examinations. In addition to the dilemma posed by the patient with preleukemia, patients with CML who present in blast crisis (Chapter 48) and patients with myelofibrosis who have increased myeloblasts in the marrow or even in the blood (Chapter 57) must be differentiated. As reviewed in Chapters 48 and 57, other features suggesting those diseases often allow the correct diagnosis to be made.

Patients recovering from neutropenia (Chapter 41) or aplastic anemia (Chapter 56) may have a marrow in which myeloblasts and promyelocytes predominate if the specimen is obtained when neutrophil production is recovering. For this reason the patient who appears to have "aleukemic leukemia" (page 1482) should be observed for a short time to be certain that the blastic marrow does not mature or that neutrophils do not return to the blood before a firm diagnosis of leukemia is made, unless other features also suggest the diagnosis. We have observed one 17 year old boy, who has been neutropenic since birth, in whom repeated bone marrow aspirates contain 30 to 45% monocytoid myeloblasts and promyelocytes but virtually no myelocytes or more mature cells. It only has been the knowledge of prolonged neutropenia and the absence of anemia or thrombocytopenia that has allowed us to exclude a diagnosis of AML.

Miliary tuberculosis has been reported to produce a leukemoid reaction indistinguishable from AML (Chapter 41), even with Auer rods in the myeloblasts.<sup>110</sup> However, we have seen no reports of successful antituberculosis therapy which induced hematopoietic recov-

ery in such cases. The patients may well have had AML as well as tuberculosis rather than having a leukemoid reaction.

Tumor cells in bone marrow, especially in neuroblastoma,<sup>67</sup> may be confused with lymphoblasts (Plate XXIV). These cells tend to occur in clumps while leukemic blasts are fairly uniformly distributed in marrow smears or biopsy specimens. The cells of infectious mononucleosis (Chapter 43) should not be confused with lymphoblasts by the skilled morphologist.

Other conditions in which myeloblasts and promyelocytes have been observed in the blood include severe pyogenic infections, acute hemolytic anemia, metastatic tumors, dehydration, and juvenile rheumatoid arthritis.<sup>92</sup> This type of leukemoid reaction (Chapter 41) seems more common in infants and young children than in adults and the blood usually suggests CML rather than AML.

## Course, Complications, and Cause of Death

The course of acute leukemia may be favorably or adversely affected by therapy. The chief causes of 90% of deaths and of much of the morbidity reflect two of the common presenting complaints—hemorrhage due to thrombocytopenia and infection due to neutropenia (Table 47-4).<sup>19,109</sup> Fatal hemorrhages in AML are usually subarachnoid, but a significant number of patients die from gastrointestinal hemorrhage or from intracerebral hemorrhage associated with a rapidly rising white blood cell count and leukostatic cerebral lesions (Chapter 54). Leukostatic cerebral lesions are more often found in AML than in ALL patients, while fatal gastrointestinal hemorrhage is more common in those with ALL than in AML.<sup>19,84</sup> Occasionally, fatal hemorrhage into bronchi, pericardium, or peritoneum is encountered. Liberal use of platelet transfusions (Chapter 54) reduces the frequency of fatal hemorrhage in acute leukemia. The proportion of patients at the National Cancer Institute dying of hemorrhage decreased, while the proportion

dying of infection increased over a 10-year period (Table 47-4),<sup>84</sup> a change attributed to the increased use of platelet transfusions. In this study the type of fatal infection changed during the same period; staphylococcal infections decreased and fungal infections increased, a change presumably attributable to changed antibiotic usage (Chapter 54).

Other demonstrable causes of death include leukemic infiltration producing hepatic, pulmonary, cardiac, or renal failure, as well as meningeal lesions (Chapter 54).

The primary causes of death are also the primary complications and causes of morbidity during life (see Chapter 54). However, since some infiltrating lesions which are life-threatening, such as *meningeal infiltration*, can be corrected by local therapy (Chapter 54), these constitute more common causes of morbidity than mortality in properly managed patients. Meningeal infiltration is much more frequent in ALL than in AML. This perhaps simply reflects longer survival in ALL for, as discussed in Chapter 54, such infiltration may occur during periods of hematologic remission as well as with active disease.

Anemia, with its concomitant symptoms and signs, must be combatted by judicious use of transfusions in almost all patients with active disease. Fever, in the absence of infection, may be accompanied by severe or by minor symptoms (Chapter 54). Complicating infection is common during any period of active disease<sup>45</sup> (Chapter 54) and can develop even during remission if maintenance therapy is sufficiently intense to be immunosuppres-

sive.<sup>22,131</sup> Early recognition and prompt, specific antimicrobial chemotherapy are necessary if infections in a leukemia patient are to be controlled (Chapter 54). It was suggested that adjunctive therapy, that directed toward treating complications rather than toward systemic control of leukemia, prolonged life before effective chemotherapy was introduced.<sup>14</sup>

## Survival

The duration of life after diagnosis of AML with or without therapy is quite variable. Survival curves for three series of patients treated by us are shown in Figure 47-5B. Patients treated before effective therapy was available lived an average of 2.5 months, many dying very shortly after diagnosis; only rarely did patients live more than a year. These results were similar to those in comparable series.<sup>65</sup> Survival in patients who were treated with 6-MP but failed to achieve remission was virtually identical to that of patients given no effective therapy. In those in whom remission was induced by therapy, life was prolonged. With modern combined drug therapy (page 1494) the percentage of AML patients achieving complete remissions has increased<sup>7a,36a,40,141</sup> and some have survived two years or longer.<sup>7a</sup> However, as many as 25<sup>36a</sup> to 32<sup>7a</sup> % have died in four to six weeks because of marrow hypoplasia induced by therapy or due to the disease itself.

Many factors influence survival, including the drugs used, patient age, facilities avail-

**Table 47-4. Changing Causes of Death in Acute Leukemia at the National Cancer Institute**

Cause of Death	Total Group (366 Patients)	1954-1959 (124 Patients)	1960-1963 (131 Patients)
Infection	38%	27%	48%*
Hemorrhage	21%	27%	14%*
Infection and hemorrhage	32%	40%	24%*
Other	6%	5%	7%
Obscure	4%	2%	7%

\*Differs significantly from 1954-1959 figures (Modified from Hersh<sup>84</sup>)

able, and professional experience.<sup>67</sup> We achieved better results with 6-MP in the second seven years of its use than in the first. Increased familiarity with the drug probably was an important factor.<sup>20</sup> Survival of patients with ALL treated at "centers" has been shown to be markedly superior to survival of patients treated elsewhere in the United States<sup>117</sup> and Great Britain.<sup>2</sup>

Very significant prolongation of life has been achieved in patients with ALL (Figs. 47-5A and 47-6). Before the introduction of steroids and folic acid antagonists in 1948-49,<sup>54</sup> survival was quite similar to that of AML.<sup>79,139,173</sup> It has been steadily prolonged as new drugs have been introduced; median survival now exceeds three years in some series.<sup>91,134</sup>

Whether or not a remission is achieved by therapy, there are innate features of the disease at the time of diagnosis that influence survival. Obviously, the patient who presents with life-threatening hemorrhage or infection may die before platelet transfusions or antibiotics become effective. The number of blasts in the blood also influences survival.<sup>12,19,52,65,118,188</sup> This has been recognized for more than 50 years.<sup>7</sup> Ineffectively treated patients with more than  $100 \times 10^9$  blasts/l lived an average of only one month and none survived for six months in our series. Conversely, ineffectively treated patients with fewer than  $10 \times 10^9$  blasts/l lived an average of five months and 20% lived for a year or more. Similarly, remissions lasted longer in patients with low blast counts at diagnosis than in those in whom the count was high, although the rate of remission induction in ALL was similar in the two groups.<sup>19,63</sup> Independently of the blast count, the presence of sternal tenderness was also found to be a relatively poor prognostic sign.<sup>19</sup> Since blast count could not be correlated with organ size and since organ size could not be correlated with survival in most<sup>19,125</sup> but not all<sup>77</sup> studies, it remains uncertain whether or not the total number of leukemic cells borne by the patients influences prognosis. The breakdown of undefined normal marrow release mechanisms (Chapter

2) probably is not as great in patients with few blasts in the blood as in those with many, and one might speculate that the better survival in the former group reflects better maintenance of normal control mechanisms. Age appears to be an important factor in determining response to therapy and survival.<sup>50</sup> Adults with ALL lived a slightly, although not significantly, shorter time than did children in our<sup>19</sup> and in certain other<sup>12,129</sup> series, and did significantly less well than children in other series.<sup>13,82</sup> The remission rate in patients with AML over the age of 60 may<sup>20</sup> or may not<sup>71a</sup> be lower than in younger ones, even though the general features of the disease appear to be much the same in both groups. There is some suggestion that Negro patients with ALL do less well than Caucasians.<sup>178</sup> Low platelet levels have been reported to suggest poor prognosis in some<sup>12,52</sup> but not other<sup>19,183</sup> series. Obesity and a long period of symptoms before diagnosis were regarded as indicators of poor prognosis in one study,<sup>183</sup> but duration of symptoms bore no relation to survival from the time of diagnosis in other series.<sup>19,188</sup> The presence of anergy may be a poor prognostic sign in acute leukemia,<sup>85</sup> but this has been disputed.<sup>72a</sup> There is a suggestion that females with ALL fare better than males.<sup>13</sup>

## Therapy

### General Principles

The management of acute leukemia, like that of any other fatal illness, requires all the art and scientific acumen of the physician. The physician must be skillful in management of the psychologic aspects of the disease (Chapter 55) as well as the somatic features. The goal of therapy is to reduce morbidity and prolong life. In acute leukemia this usually can be equated with induction of a complete remission(s) and maintenance of the patient in complete remission for as long as possible. During trials of remission induction, vigorous therapy of complications is mandatory. Prophylactic administration of platelets when severe thrombocytopenia is

Fig 47-5 To show the steady improvement in survival of patients with acute lymphoblastic leukemia (A) in the successive periods (reading from left to right) 1947-1954 (—○—), 1954-1957 (—●—) and 1958-1964 (—○—), as well as in patients treated with a preferred method of sequential therapy (—●—) 117

The survival of patients with acute myeloblastic leukemia (B) improved only slightly in the same periods of time (1947-1954, —●—, 1954-1957, —●—, 1958-1964 —○—)

present may be advisable (Chapter 54) and serious bleeding should be treated by platelet transfusions until it has ceased (Chapter 54). Careful evaluation of fever or of any complaint suggesting infection is essential since prompt, specific antibiotic therapy is necessary in treating infection in neutropenic patients (Chapter 54). Good hydration and

urine flow as well as allopurinol administration are important in avoiding urate nephropathy (Chapter 54). Corticosteroids, vincristine, and asparaginase—useful remission-inducing agents in ALL—usually do not induce depression of normal blood cells (Chapter 55). However, all other agents in use poison normal as well as leukemic

Fig 47-6. Changing survival of patients under 20 with acute lymphoblastic leukemia entered in acute leukemia group B protocols. 'Diagnosis' refers to the years when the diagnosis was made. As the years have progressed the chemotherapy has become more and more intensive and a variety of drugs have been added. Regimen D refers to children included in the 1966-67 curve who had been induced into remission with vincristine and prednisone and had received three courses of methotrexate. Prior to 1960 no child survived five years. In each subsequent grouping, the five-year survival has increased. (From Holland<sup>21</sup>; courtesy of the author and Pediatrics.)

cells. Even when remission follows their use, a period of increased thrombocytopenia and neutropenia ensues during the initial stages of therapy. It is during this cytopenic, pre-remission stage that adjunctive therapy (Chapter 54) has its greatest value. The advisability of vigorous therapy of hemorrhage and infection in patients for whom no drugs which are likely to induce remission are available is more debatable.

The original criteria agreed upon for definition of remission can be generally stated as: *Complete remission*—an asymptomatic patient with no physical abnormalities; normal hemoglobin, leukocyte, and platelet blood values; and normal-appearing bone marrow. *Partial remission*—marked improvement but with some residual evidence of disease. These were defined in some detail<sup>15</sup> so that reports from different centers would be comparable. However, these standardized criteria have not

been used routinely so that the reader must be somewhat wary of comparing the frequency of reported remissions in different series. As toxic regimens of remission-maintenance therapy have been developed (page 1491) the criteria for lack of morbidity and for normal blood values have sometimes been dropped from the definition of remission and emphasis has been placed on the absence of increased blasts in the bone marrow.

It should be noted that, even in the presence of "complete remission," careful study may reveal residual leukemic cells in organs such as the liver and kidneys.<sup>119,155</sup> In addition, it is now well recognized that meningeal infiltration can occur during remission (Chapter 54).

A decision to interrupt therapy because of thrombocytopenia or neutropenia during remission induction requires careful evaluation

of the patient as well as considerable experience with the disease. If no blasts are present in the blood or marrow, therapy should be stopped until neutropenia and thrombocytopenia improve or until blasts return. Conversely, if blasts are still present in the blood or if they are numerous in the marrow the proper course may be to continue chemotherapy at full dosage despite increasingly severe neutropenia or thrombocytopenia. With residual but seemingly reduced blasts, reduced dosage or transient interruption of therapy may be in order. While one can design hard-and-fast rules for management, as is done for experimental therapy protocols, the physician experienced in chemotherapy individualizes his decisions.

It should be emphasized that prolonging life with chemotherapy in acute leukemia need not cause a corresponding increase in the duration of morbidity during the course of the disease. If drug toxicity has been avoided during remission and if relapse is detected at an early stage, the patient may be kept in a relatively asymptomatic state from the onset of the initial remission until the terminal phase of the disease (Fig. 47-7).

### Therapy of ALL

It is generally agreed that chemotherapy should be started in all patients as soon as the diagnosis of ALL has been established. Therapy of meningeal infiltration or prophylaxis for such infiltration (Chapter 54) is as essential as systemic chemotherapy in these patients.

#### Remission Induction

Remission can be induced by a wide variety of agents, given singly or in combination (Table 47-5). Prednisone, vincristine, and asparaginase induce remission usually without toxic effects on normal marrow cells (Chapter 55). Thus, their use avoids the period of increased cytopenia which often presages remission induced by other agents. A very widely used regimen for initial treatment is prednisone-vincristine therapy; this

results in complete remission in about 90% of patients (Table 47-5). Prednisone is given by mouth in a daily dose of 1 to 2 mg/kg and need not exceed a total dose of 60 mg/day,<sup>174</sup> while vincristine is injected intravenously once a week, approximately 2 mg/m<sup>2</sup>/week, not exceeding a total dose of 2 mg<sup>50</sup> (Chapter 55). Use of these drugs is continued until complete remission has been achieved, until neurotoxicity from vincristine appears, or for a maximum of six weeks. If neurotoxicity interrupts vincristine therapy, prednisone should still be given. Complete remission usually is achieved by four weeks and, if remission is not attained by six weeks, its subsequent development is unlikely and therapy should be changed. Starting a "maintenance" drug such as 6-MP will often induce remission in patients who at that point have improved but are not in remission.<sup>19,66</sup> Larger doses of prednisone may result in slightly more rapid remission induction but do not result in a higher remission rate.<sup>113,154</sup> Intermittent prednisone therapy, though less toxic, is inferior to continuous therapy in inducing remissions.<sup>113</sup> Doses of vincristine lower than 2 mg/m<sup>2</sup>/week may induce a smaller number of remissions,<sup>60</sup> but if more than a total dose of 2 mg is given, neurotoxicity may be severe (Chapter 55). Alternatively, prednisone alone may be used. Remission is induced in more than 50% of cases (Table 47-5) and improvement occurs in almost all patients. If remission has not been achieved, vincristine can then be given; the eventual remission rate is similar to that observed when the drugs have been used in combination.<sup>153</sup>

With relapse from the first remission, prednisone and vincristine often are again effective; these drugs may induce three or more consecutive remissions (Table 47-6).<sup>107,161</sup> However, repeated use of vincristine must always be tempered by the degree of previously observed neurotoxicity. Addition of daunomycin to prednisone and vincristine in second, third, and fourth remission-induction attempts did not prove beneficial.<sup>99,175</sup>

The use of four drugs in combination, as in the "POMP" or "VAMP" regimens,<sup>32</sup>

Fig. 47-7 Long remission following administration of 6-mercaptopurine in an adult patient (S D) with acute myeloblastic leukemia

results in enough toxicity that the equivocal increase in rate of remission induction does not of itself justify their use. Indeed, one of the first cooperative group studies<sup>62</sup> indicated that inducing severe toxicity with 6-MP or MTX did not enhance the remission rate. Possible justification for their use on the basis of longer duration of remission is discussed below.

When prednisone with vincristine becomes ineffective in remission induction, asparaginase probably is the drug of choice, being effective in about 50% of patients (Table 47-5). A recommended dose of asparaginase has not been established but 10,000 units/m<sup>2</sup> once a week may be as effective as higher doses and is less toxic.<sup>135</sup> The use of other agents listed in Table 47-5 for remission induction depends on whether the drug has or has not been used in maintaining prior remissions. If relapse occurs during full dosage of a chemotherapeutic agent, the drug no longer is of any future benefit to the patient except under unusual circumstances.<sup>19,65</sup> However,

MTX, when used in intermittent intravenous dosage, has induced remissions after relapse occurred during daily oral therapy.<sup>132</sup> The effectiveness of certain remission-inducing agents is heavily dependent upon the severity of the disease. Cyclophosphamide will induce remissions if it has been started early in relapse but is rarely effective in the severely ill patient<sup>133</sup> (Table 47-5).

In general, the chance of inducing a remission with a given drug is independent of whether it is used initially or in subsequent relapses. For example, the remission rate with 6-MP was virtually the same when used in untreated patients or in those relapsing from an MTX-induced remission and the same was true for MTX used initially or after a 6-MP-induced remission.<sup>1</sup>

### Maintenance Therapy

Unless effective therapy is continued during remissions induced by prednisone or prednisone and vincristine, relapse occurs

quite quickly in ALL patients (Table 47-7). Certain drugs that are quite useful as remission-inducing agents are not effective in maintaining the remission once it has been achieved (Table 47-7). For example, in controlled clinical trials, the duration of steroid-induced remissions was not prolonged by continuing steroids after remission was achieved.<sup>97</sup> Drugs given as single agents which have proven remission-maintenance properties are MTX, 6-MP, and cyclophosphamide,<sup>56</sup> although in one study<sup>133</sup> cyclophosphamide was of questionable benefit in maintenance (Table 47-7). The timing of doses can be as important as the specific drug used. Given in maximally tolerated daily doses, MTX is inferior to 6-MP as a remission-maintenance drug,<sup>19</sup> but when MTX is given twice each week in a dosage of 30 mg/m<sup>2</sup> of body surface it becomes the best-known single agent (Table 47-7). Such observations suggest that more optimal dosage schedules might be found for other drugs. Intermittent therapy cannot be considered universally superior to daily therapy, however, since intermittent cyclophosphamide proved inferior to daily dosage in remission induction.<sup>133</sup> If one wishes to maintain remission with a minimum of toxicity the first

remission should probably be maintained with a twice weekly administration of methotrexate and the second and third with daily oral doses of 6-MP and cyclophosphamide, respectively. Drugs such as 6-MP and MTX have been given in sequential rotations every four to eight weeks in an attempt to delay development of resistance to the drugs. However, the total duration of time in remission was not increased by such regimens,<sup>63</sup> nor was it increased by combination 6-MP-MTX maintenance<sup>1,63</sup> (Table 47-7). Multiple drug and "reinduction" maintenance regimens are discussed below and experimental concepts such as immunotherapy, which has been reported to be effective in certain studies<sup>150</sup> but not in another,<sup>96</sup> are considered in Chapter 55.

### Long Remissions, "Cure," and Intensive Combination Chemotherapy

A few "cures" were reported before the advent of remission-inducing therapy in acute leukemia. Spontaneous remissions of short duration<sup>23</sup> were well documented and there was at least one convincing report of a patient remaining well for some years.<sup>146</sup>

After the introduction of chemotherapy with induction of remission, a few patients were observed who remained (and continue to remain) in remission for many years. The longest known remission was 21 years as of 1972, and at least 93 patients were known to be alive and in remission for nine or more years.<sup>27</sup> The patient with the longest remission in our series was 19 years of age when the diagnosis of ALL was made in 1959. She developed a complete remission with prednisone therapy, was maintained with daily 6-MP for approximately five years, and remains in remission. Most long-term survivors have been children with ALL, but also among them are adults with ALL and patients of all ages with AML.<sup>13,27</sup>

Such observations raise hope that a few patients with acute leukemia have been cured. The difficulty in defining a cure lies in the observation that a number of patients have been reported who experienced relapse in the fifth and sixth years of remission, and relapse after 11,<sup>55</sup> 12, and 16<sup>27</sup> years has been noted. Intensive chemotherapy (see below) probably leads to a higher percentage of patients achieving five-year remissions<sup>134</sup> than does single-drug induction and maintenance therapy.<sup>19</sup> Simply stated, the current dilemma in the treatment of patients with ALL concerns the question of whether or not patients have been cured. If so, then the morbidity and expense associated with aggressive combination chemotherapy are easily justified; if not,

**Table 47-7. Duration of Complete Remission in Children with Acute Lymphoblastic Leukemia**

<i>Method of Induction</i>	<i>Number of Patients</i>	<i>Maintenance Therapy</i>	<i>Median Duration of Remission (Weeks)</i>

	21	'half dose'	71

\* POMP, VAMP, and BIKE refer to prednisone, vincristine, 6-MP, and MTX combined. Dosage is higher in POMP than in VAMP or BIKE. BIKE means two cycles of these drugs. HN2 refers to nitrogen mustard.

its justification is less apparent. The rationale of intensive combination chemotherapy is the concept that every leukemic cell can be killed, a concept presently based on certain unproven assumptions (Chapter 55). Unfortunately data adequate to make one certain of cure are not available. Cure might be defined by demonstrating a marked lessening of the chance of relapse with each successive year of remission, as has been shown in HD (Chapter 50). This has been postulated in the case in ALL<sup>27</sup> but there has been no evident reduction with time as to the chance of relapse in the series of 165 patients with ALL, known to have remained in remission for at least four years.<sup>13</sup>

Induction therapy with toxic doses of 6-MP, MTX, prednisone, and vincristine ("POMP")<sup>83</sup> has not significantly increased the percentage of remissions over that observed after prednisone and vincristine therapy (Table 47-5). However, the duration of unmaintained remission has been much longer after "POMP"-induction therapy (Table 47-7). Evidence that the duration of unmaintained remission bears a direct relation to the intensity of induction therapy is also found in the observation that "POMP"-induced remissions are longer than "VAMP" or "BIKE" remissions, regimens using the same four drugs contained in "POMP" but at lesser dosage.<sup>32, 83</sup> Intensive adjunctive therapy (Chapter 54) with frequent platelet and leukocyte transfusions, intensive antibiotic therapy for complicating infections, and prolonged hospitalization are required for the use of "POMP" and many other combinations discussed below. The high mortality associated with "VAMP" therapy in centers other than those specifically devoted to treatment of acute leukemia attests to the toxicity of the regimens.<sup>171</sup> Nevertheless, long remissions can be obtained by intensive treatment of children relapsing from remission<sup>6</sup> as well as in previously untreated patients.

Consolidation therapy employs the concept that a brief period of intensive therapy immediately following induction of complete remission should prolong the remission. For example, the effect of a brief, intensive course

of MTX following prednisone and vincristine remission induction is under study.<sup>12, 13</sup>

Reinduction therapy is a term applied to the periodic treatment of the patient who is in remission. The type of treatment is similar to that which might be given if he had experienced relapse. When at various intervals different regimens of combined drugs have been given in toxic dosage,<sup>12, 134</sup> the duration of remission has proved to be longer than that seen with single-drug maintenance. The number of available drugs (Table 47-5) and the almost limitless possibilities of time and dose schedules have led to numerous studies of different combinations of drugs for induction, consolidation, maintenance, and re-induction.<sup>12</sup> Even agents which are not effective in inducing remission in ALL, such as nitrogen mustard, BCNU, and actinomycin D, appear to prolong remissions when used in combination with known useful drugs<sup>12</sup> (Table 47-7). Addition of local irradiation to areas other than the CNS which are likely to contain "residual" leukemic cells failed to prolong remission.<sup>156</sup> The results of a few such treatment schedules are indicated in Table 47-7. Death from infection during remission is not uncommon with these regimens and seems to relate as much to immunosuppression as to neutropenia.<sup>22, 134</sup> A number of centers are giving vigorous therapy for two to three years and then discontinuing therapy in those patients who are still in remission.<sup>105, 134</sup> Fifteen children who had been in continuous, maintained remission from  $2\frac{3}{4}$  to  $3\frac{1}{2}$  years were randomized to continue or discontinue maintenance therapy.<sup>105</sup> During the following two years, relapse occurred in two of the seven who were maintained and in one of the eight who were not maintained, suggesting that long-term therapy is not necessary.

### Therapy of AML

The vast majority of patients with AML probably should be started on chemotherapy as soon as the diagnosis has been established since most are severely symptomatic or will become so shortly. Occasional patients, espe-

cially elderly ones considered by some as having "smoldering" leukemia, may remain in a relatively comfortable state with no therapy.<sup>102</sup> There is no clearcut evidence that some patients with morphologic variants of AML respond better or worse to therapy than do others.<sup>13,20</sup>

### Remission Induction

Three drugs are of unequivocal benefit in the therapy of AML—6-mercaptopurine (or its analog thioguanine [TG]), cytosine arabinoside (CA), and daunomycin (DN). These can be used as single agents, a second to be used if the first fails, or in combination.

**6-MERCAPTOPYRINE (6-MP).** This drug did not have very impressive remission-inducing properties when used as a single agent in our series of patients (Table 47-8).<sup>20</sup> Fewer than one fourth of the patients achieved a complete or partial remission. However, treatment with this drug is relatively easy and sometimes is successful for a time (Fig. 47-7). Other series of similarly treated patients indicate similar or even lower rates of remission.<sup>12,48</sup> The drug is given orally at a dose of 2.5 mg/kg per day and, unless therapy must be interrupted because of toxicity (Chapter 54), should be given for from six to eight weeks. If there has been no improvement in levels of erythrocytes, reticulocytes, platelets, or neutrophils by eight weeks, use of the drug should be stopped since there is almost no chance that remission will occur with more prolonged therapy. If any of these parameters are improving, therapy should be continued as long as improvement persists. Blasts should disappear from the blood within the first four weeks of therapy in patients who are likely to develop remission. However, modest increases in blasts in the marrow persist during partial remissions. Thioguanine, a close analog of 6-MP, has the same spectrum of action as a single agent in AML as 6-MP.<sup>104</sup> Since the metabolism of TG is not affected by allopurinol, TG is probably preferable to 6-MP during periods of allopurinol use. If remission occurs, most recommend continuing 6-MP as maintenance therapy as long as remission persists. How-

ever, there has been no study which proves that maintenance therapy prolongs remission in AML as it does in ALL (page 1491).

**CYTOSINE ARABINOSIDE (CA, ARA-C).** Given as a single agent, CA may be a slightly better remission-inducing agent than 6-MP<sup>32</sup> (Table 47-8). The presently preferred regimen appears to be one of intermittent therapy. However, a wide variety of schedules has been tried and the best method of administration is not established as yet<sup>32</sup> (Chapter 55). An example of a currently used schedule is as follows: an iv injection of 100 mg/m<sup>2</sup> total dose/day of CA is given every eight hours for a period of five days. No therapy is given for the next 10 days and this cycle is then repeated. If a remission is obtained, marked improvement is usually noted by the third cycle. As good or perhaps even better results are obtained when CA is given daily for four days in four-hour infusions of 70 to 150 mg/m<sup>2</sup>.<sup>71</sup> Whether maintenance should be with periodic courses of CA or with 6-MP, or both, is unsettled.

**DAUNOMYCIN.** Given as a single agent, daunomycin has produced a higher percentage of remission than either 6-MP or CA<sup>74</sup> (Table 47-8). When given daily for three to five days, followed by a rest and then repeated, a higher percent of remissions was induced than when it was given once a week.<sup>13</sup> The best current regimen may be to give 60 to 80 mg/m<sup>2</sup> iv once a day for three days, wait five days, and repeat the three-day courses once or twice if myeloblasts are still present. Cardiac toxicity (Chapter 55) is unusual if less than a total of 600/m<sup>2</sup> is given, but marrow toxicity (Chapter 55) is severe and somewhat unpredictable. Daunomycin alone proved superior to the four-drug combination, "POMP," in a randomized trial yielding 50% CR as compared to 29%.<sup>184</sup> Adriamycin, a close structural analog of daunomycin, has not appeared to be as useful in AML as daunomycin.<sup>33</sup>

**COMBINED CA AND 6-MP OR TG.** In the hope that the drugs would prove synergistic, or at least additive, various schedules for combined administration have been tested.

Table 47-8. Remission Induction in Acute Myeloblastic Leukemia

Drug	Number of Patients	Percent of Patients with		
		Complete Remission	Partial Remission	Total Remissions
6-Mercaptopurine <sup>20</sup>				
1952-1960	70	12	4	16
1961-1968	76	22	8	30
6-Mercaptopurine <sup>54*</sup>	31	10	6	16
Methotrexate <sup>19</sup>	34	3	3	6
6-MP and MTX <sup>42</sup>	36	14	3	17
Cytosine arabinoside <sup>32*</sup>	360	21	7	28
Daunomycin <sup>13</sup>	43	56	?	56+
Literature summation	211	34	7	34+
Daunomycin <sup>72</sup>	71	25	15	40
Cytosine arabinoside and 6-thioguanine <sup>32*</sup>	31	—	—	45
Vincristine, daunomycin and cytosine arabinoside <sup>141</sup>	23	48	4	52
L-asparaginase, daunomycin and cytosine arabinoside <sup>40</sup>	23	56	4	60
Cytosine arabinoside prednisone vincristine and cyclophosphamide (COAP) <sup>32*</sup>	45	—	—	47
Hydroxyurea, cytosine arabinoside and 6-thioguanine <sup>73†</sup>	31	42	26	68

\*Based on "evaluable" rather than total cases entered

To date, results of relatively small series suggest that their effect will be additive at best (Chapter 53) (Table 47-8), the results being those predicted on the basis of their individual effects rather than being attributable to synergism<sup>56</sup> (Table 47-8). A variety of other combinations of drugs has been tried with rather variable results (Table 47-8).<sup>13,21,32,52,70,141</sup> In 1971, results of therapy in at least 31 series of more than 20 adults with AML had been reported.<sup>70</sup> In only four such series did complete remission rate reach 50%, three with daunomycin alone and one with a four-drug combination.

**OTHER AGENTS.** The use of steroids in AML remains a controversial topic. Shortly after these agents became available it became apparent that they were primarily useful in ALL and of little benefit in AML.<sup>57</sup> Spontaneous remissions develop in AML with a frequency of approximately 5%<sup>64,151</sup> and the remission rate with steroids as a single agent did not exceed 5% in our series.<sup>19</sup> Shanbron<sup>154</sup>

likewise failed to note improvement. Other series have reported improvement with steroid therapy in a significant number of patients said to have AML (see refs 19 and 142). It has been suggested that steroids may accelerate the course of AML.<sup>55,68</sup> When combined with 6-MP it has been reported that steroids are harmful or beneficial or have no effect.<sup>19,187</sup> Considering the conflicting literature, we are unconvinced that adrenocorticosteroids have any appreciable efficacy in AML and, in view of their undesirable side effects, rarely use them. Hydroxyurea fails to induce a significant number of remissions in AML (1 in 67 trials) but, combined with prednisone, a small but significantly higher number of remissions (8 in 52 trials) occurred.<sup>142</sup>

*Methotrexate* is of little or no benefit in an oral daily dose either as a single agent<sup>19</sup> or combined with 6-MP.<sup>56</sup> However, when given orally or iv, at fairly toxic dosage on an intermittent basis, remissions have been reported.<sup>177</sup> *Methyl-GAG* (methylglyoxal-

bis-guanyldiazotization)<sup>115</sup> induces a significant number of remissions in AML but is exceedingly toxic (Chapter 55). Cyclophosphamide,<sup>83</sup> vincristine,<sup>83</sup> and asparaginase<sup>83,128,169</sup> are among the rather large group of agents (Chapter 55) that have been administered in AML with modest or equivocal effects.

The duration of remissions, even complete remission, may be rather short. In one review of 96 complete remissions in AML, median duration of remission was 4.2 months with a mean of 6.3 months and a range of 1 to 18 months.<sup>153</sup>

are young or middle-aged adults. This form of leukemia is more frequent in males than in females by a ratio of approximately 3:2.

### Classification

In terms of predictability of the course and responsiveness to therapy, at least two types of CML can be distinguished on the basis of the presence or absence of the Philadelphia chromosome (Table 48-1). There also are differences in clinical manifestations, course, and survival in patients whether they do or do not have the  $Ph^1$  abnormality (page 1512). A possible sub-set of the  $Ph^1$ -positive group has been suggested.<sup>36</sup> These patients lack the Y chromosome. They may be designated as 45, XO,  $Ph^1$ , indicating that they are aneuploid, due to a missing Y chromosome (XO), and have the  $Ph^1$  abnormality.<sup>36</sup> There is a suggestion that 45, XO,  $Ph^1$  confers a particularly good prognosis even though the hematologic and clinical findings otherwise seem to be identical to those of 46, XY,  $Ph^1$  patients (page 1509).<sup>36</sup> In addition, eosinophilia, basophilia, or monocytosis has been so prominent in some patients that such subtypes have been distinguished (page 1513).

### Presenting Features

The symptoms, signs, and laboratory findings present at the time of diagnosis in patients observed at the University of Utah

THE historical development, definition, and classification of leukemia in general as well as the specific place of chronic myelocytic leukemia (CML) in such a classification have been discussed, as have such aspects of CML as its possible clonal nature, etiology, pathogenesis, and incidence (Chapter 46). Chronic myelocytic leukemia is characterized by extreme elevation of the leukocyte count as a result of the presence of increased numbers of all forms of mature and immature granulocytes. It can be observed at any age, but increases steadily in age-adjusted frequency throughout life. Thus, considering the age distribution of the population of the United States, most patients seen with CML

### Symptoms

The diagnosis of CML may be made at a time when the patient is asymptomatic. As in a British series,<sup>124</sup> in 15% of our series<sup>75</sup> the diagnosis was made at such a time. These patients are found to have an elevated leukocyte count or a palpable spleen on routine examination or in conjunction with examination for unrelated illnesses. Symptoms may develop rapidly, fatigue and anemia appearing within six months after the diagnosis has been made. However, an asymptomatic period of some years' duration may be observed occasionally.<sup>12,77,81,123</sup> In patients in whom the diagnosis is made at an early stage the great majority of the blood cells are mature; only rarely are metamyelocytes and myelocytes seen.

The median duration of symptoms before the diagnosis was established was three months in our series of patients.<sup>75</sup> This is a much shorter pre-diagnostic, symptomatic period than had been noted in earlier series.<sup>79,105</sup> Perhaps, because of improving medical care patterns, the diagnosis is made at an earlier stage of disease at the present time than it was some years ago. Typical presenting symptoms of patients with CML are fatigue and/or discovery of a mass in the left upper quadrant of the abdomen, or discomfort in the left upper quadrant. Less

\*Patients seen at the University of Utah Hematology Clinic<sup>75</sup>

(Chapter 30), compared with the general population there is a higher frequency of peptic ulceration of the stomach or duodenum in patients with CML, but the reason for this association is unknown. Fourteen percent of our patients with CML had radiologically documented peptic ulcers and others had symptoms suggestive of peptic ulceration. Complaints of bone pain or symptoms related to compression of the spinal cord<sup>40</sup> or priapism<sup>26,40</sup> are unusual, but are quite distressing when present. Anorexia and weight loss are common, but rarely are severe.<sup>34</sup> Fever may occur (Table 48-2), but it is rarely due to a documented infection until late in the course of the disease.<sup>9</sup>

### Physical Findings

The most common signs are splenomegaly, pallor, and sternal tenderness (Table 48-2). Hepatomegaly, lymphadenopathy, purpura, and fundic hemorrhages also are detected frequently. Roentgenograms of the lungs or of bone usually show no abnormality. The spleen is quite variable in size ranging from a just palpable tip to a mass filling the left side of the abdomen. In 71% of patients in one series<sup>21</sup> and in 40% of our patients<sup>75</sup> the spleen extended more than 10 cm below the costal margin at the time of diagnosis. Spleen size correlates reasonably well in a positive fashion with the height of the leukocyte count. The spleen is quite firm, usually non-tender unless splenic infarction is present (Chapter 54), and the splenic hilum (notch) may be palpable. Sternal tenderness is a reliable sign of disease and usually is limited to a small area, most commonly in the mid-body of the sternum. If true sternal tenderness is present the patient will withdraw or spontaneously complain when firm pressure is applied to the tender area, but he will have been previously unaware of its existence. Palpable lymph nodes are present in the majority of patients, but rarely are large. Nodes estimated to be greater than 1 cm in largest diameter were present in less than 10% of our patients.<sup>75</sup>

### Laboratory Studies

The leukocyte count (Table 48-3) is higher than  $100 \times 10^9/l$  in 62%<sup>75</sup> to 90%<sup>124</sup> of patients at the time the diagnosis is made and may be in excess of  $1000 \times 10^9/l$ . All stages of the neutrophilic series from myeloblasts to segmented neutrophils usually are present. Segmented and band neutrophils usually are the most common cells, followed in decreasing order by metamyelocytes, myelocytes, promyelocytes, and myeloblasts. Promyelocytes and myeloblasts make up only a small percentage of the total number of cells until blast crisis supervenes. However, there is a direct relationship between the height of the leukocyte count and the percentage of immature cells at the time of diagnosis.<sup>72,75</sup> In excess of 20% blasts and promyelocytes often is considered to signify blast crisis (page 1514), but that percentage may be present in previously untreated patients with a very high leukocyte count in the absence of blast crisis. Rarely, mature neutrophils remain the predominant blood leukocyte throughout the course of the disease (chronic neutrophilic leukemia<sup>19,27,81,107</sup>). Basophils are increased in absolute number in almost all patients as are eosinophils and monocytes and the latter cells may be mistaken for myelocytes. The absolute lymphocyte count usually is within normal limits.

In most untreated patients the leukocyte count increases progressively (Fig. 48-1). However, in some, cyclic variations in the count are noted<sup>215,80,118</sup> (Fig. 48-2). The count may rise and then fall by more than  $200 \times 10^9/l$  during such cycles and cyclical changes have been noted during therapy<sup>64</sup> as well as in untreated patients.

Anemia is present at the time of diagnosis in most patients, but is often mild and transfusion was required initially in fewer than 10%<sup>71,124</sup> (Table 48-3). The anemia is normochromic, red cell shape appears normal on blood smears, and the absolute reticulocyte count is normal or slightly elevated (Table 48-3). Only very rarely<sup>73</sup> is a hemolytic anemia present. Nucleated red cells may be

# PLATE XX

Blood from patients with leukemia (A, B, C, D) contrasted with normal bone marrow (E). A and B are from patients with chronic myelocytic leukemia (Wright's stain,  $\times 1000$ ). C and D are blood smears from patients with acute myeloblastic (C) and acute monocytic (D) leukemia and show a positive peroxidase reaction in all three cells from the patient with myeloblastic leukemia and in a single cell from the one with monocytic leukemia. E shows normal bone marrow elements (Wright's stain,  $\times 1000$ ).

most patients. Differential counts from marrow smears reveal an increased myeloid to erythroid ratio, but fairly orderly neutrophil maturation is found in most patients. The proportion of immature to mature neutrophils tends to be higher in marrow than in blood (Table 48-4),<sup>8,123</sup> suggesting that the barrier to release of immature cells (Chapter 2) is not lost completely. Detailed morphologic study, as by electron microscopy, shows certain abnormalities of the neutrophilic series. There is evidence that cytoplasmic maturation is more rapid than nuclear maturation, there being a greater than normal number of granules in promyelocytes in contrast to their immature-appearing nuclei.<sup>2</sup> Blasts and promyelocytes from patients with CML are more motile and have greater phagocytic potential than those from normal subjects, features which probably reflect cytoplasmic maturation.<sup>92</sup> Rod-shaped granules are more frequent than normal.<sup>94</sup> Auer rods are observed occasionally,<sup>12,121</sup> but by no means as frequently as in AML (Chapter 47). Barr bodies are less common in mature neutrophils in females with CML than in normal females, but are said to increase in frequency following therapy.<sup>116</sup> Pelger-Huet-like anomalies

(Chapter 42) may be observed, primarily in later stages of the disease.<sup>23,25,51</sup> A patient with CML and cells containing the Alder-Reilly leukocyte anomaly (Chapter 42) has been reported, but this patient was thought to have had the anomaly prior to developing CML.<sup>74</sup>

*The Philadelphia chromosome* (Chapter 46) has been reported to be present in 70 to 90%<sup>4</sup> of patients with CML.<sup>28,102,120</sup> When present, two thirds of the patients have the defect in all metaphases seen in direct preparations of marrow, while in one third a small percentage of normal metaphases is also seen.<sup>120</sup>

Erythrocyte development is morphologically normal, as is megakaryocyte maturation. Large abnormal-appearing histiocytic cells similar to those found in Gaucher's disease may be observed.<sup>62,71,98</sup> Their origin may be similar to that of Gaucher cells in that increased turnover of neutrophils produces excess cerebroside, which must be stored.<sup>62,98</sup> However, when examined with the electron microscope the cytoplasmic inclusions have a different configuration than those of Gaucher cells, so the stored substance may be different from the cerebroside of Gaucher's disease.<sup>71</sup> In one patient with

**Table 48-4. Comparison of Percentages of Various Stages of Neutrophilic Granulocytes in Marrow and Blood of 11 Patients with Chronic Myelocytic Leukemia\***

Blood	2	2	94
Marrow	33	38	29
Patient with least difference			
Blood	26	26	48
Marrow	29	29	42

\*Blood and marrow samples obtained on same day in untreated patients (Adapted from Boggs<sup>8</sup>)

CML, lacto-, rather than glucocerebroside, predominated.<sup>24a</sup>

Increased reticulum fibers may be present, but frank myelofibrosis is unusual at the time of diagnosis although it develops with some frequency later in the course of the disease (page 1506).<sup>43</sup>

*Leukocyte alkaline phosphatase (LAP)* is abnormally low and may actually be absent<sup>24</sup> in approximately 90% of patients with CML. Low LAP and Ph<sup>1</sup> positivity do not necessarily correlate; i.e., LAP may be low in a Ph<sup>1</sup>(-) patient<sup>102</sup> and may be normal or high in a Ph<sup>1</sup>(+) patient.<sup>43</sup> There is some evidence that the enzyme is chemically different in CML cells than in normal cells.<sup>11</sup> The LAP may increase in response to the development of unrelated diseases, such as ulcerative colitis, in patients with CML.<sup>97</sup> When cells from patients with CML are cultured in diffusion chambers, LAP increases, thus suggesting that there is no intrinsic defect in the ability of the cell to synthesize the enzyme.<sup>21a</sup>

*Uric acid* often is moderately elevated in the serum and almost invariably increased in the urine; gout may occur (Chapter 54). However, urate nephropathy with oliguria or anuria is unusual even during therapy so that allopurinol is not needed as often as in acute leukemia. Artifacts *hyperkalemia* may be present, probably due to in vitro potassium release from platelets as blood is allowed to stand, and artifacts *hypoglycemia* may be due to leukocyte glucose utilization in vitro.<sup>29</sup>

*Histamine* and histamine metabolite levels are elevated in plasma and leukocytes in most patients with CML<sup>4</sup>; this has been considered a possible explanation for such findings as peptic ulceration, pruritus, and asthma.<sup>41,106</sup> However, in a group of patients with CML with no symptoms attributable to histamine, plasma histamine levels averaged more than three times normal, a finding which raises doubts that any symptoms can be attributed to the raised levels of histamine in CML.<sup>114</sup> The level of histamine in blood tends to reflect the numbers of basophils.<sup>4,114</sup>

*Serum albumin* usually is normal and gamma globulin often is moderately elevated, but paraprotein spikes rarely are encoun-

tered.<sup>96</sup> *Hypercalcemia*, usually associated with bone lesions, has been described occasionally.<sup>3,71a</sup> (Chapter 54).

*Serum vitamin B<sub>12</sub>* levels as well as both total and unsaturated B<sub>12</sub>-binding capacity of serum are increased in CML, primarily reflecting elevated levels of transcobalamin I or of a third serum vitamin B<sub>12</sub>-binding protein.<sup>20,47</sup> (Chapter 4, page 139). These proteins may be synthesized by mature or maturing neutrophils<sup>109,113</sup> and their degree of increase may reflect the size of the total leukocyte pool.<sup>21</sup> Whether they are chemically different from those found in normal blood is uncertain.<sup>78,108</sup>

Transcobalamin II, the vitamin B<sub>12</sub> transport protein, is not increased in CML<sup>93</sup> and may be decreased.<sup>45</sup>

## Differential Diagnosis

A variety of conditions are associated with a blood leukocyte pattern that may mimic the pattern seen in CML. Most "leukemoid" reactions suggest CML rather than other varieties of leukemia. As discussed in Chapter 41, a variety of infections and carcinomas as well as other conditions may produce extreme degrees of neutrophilia. In most instances, absence of sternal tenderness, splenomegaly, basophilia, eosinophilia, and thrombocytosis suggests the presence of a leukemoid reaction rather than CML. A smaller proportion of the blood leukocytes is immature in most patients with leukemoid reactions, as compared to the usual patient with CML, but this is not always the case.<sup>46</sup> Cytogenetic studies of the marrow cells and LAP levels are the most definitive means of distinguishing CML from a leukemoid reaction. If the LAP is normal or raised as it is in most leukemoid reactions and if the Ph<sup>1</sup> chromosome is absent, CML is most unlikely. However, decreased LAP was reported in a patient with miliary tuberculosis.<sup>107</sup> Serum vitamin B<sub>12</sub> and transcobalamin levels may be increased in leukemoid reactions as they are in CML.<sup>18,49</sup>

In polycythemia vera (PV, Chapter 30) and in idiopathic myelofibrosis (IMF, Chapter

57), leukocytosis comparable to that seen in CML may be present, an observation which led to the concept that these are interrelated conditions constituting a "myeloproliferative disorder" (Chapter 46). Symptoms and signs of the three diseases may be quite similar although splenomegaly tends to be more extreme in IMF than in CML or PV. The size of the spleen tends to be directly proportional to the magnitude of the leukocyte count in CML so that the presence of a very large spleen with a leukocyte count of less than  $100 \times 10^9/l$  is suggestive of IMF rather than CML. The degree of immaturity of the neutrophil series, basophilia, eosinophilia, and thrombocytosis may be equal in all three conditions. However, a significant degree of anisocytosis and poikilocytosis and the presence of large numbers of nucleated red blood cells suggest IMF. A substantial amount of fibrosis in marrow biopsy specimens also suggests IMF. While fibrosis may develop during the course of CML or PV it rarely is a prominent finding at the time of diagnosis.<sup>41</sup> An abnormally low LAP makes PV an unlikely diagnosis, but the LAP may sometimes be low in IMF as it usually is in CML. The presence of the Ph<sup>1</sup> chromosome strongly favors CML although it has been described in occasional patients thought to have PV or IMF (Chapters 46 and 57). As noted below (page 1512), in patients thought to have CML, but without the Ph<sup>1</sup> chromosome, the course may be similar to that of IMF, at least as judged by their poor response to busulfan.

## Course

Until blastic crisis supervenes the symptoms and most physical and laboratory abnormalities of CML can be controlled by therapy. However, there is little evidence to suggest that therapy appreciably increases the survival time.

### Duration of Survival

Minot et al<sup>79</sup> reported the first survival figures for a large series of patients with

CML. Only those who died were included in their study. The 78 patients who were treated with irradiation, usually radium, lived an average of 3.5 years from onset of symptoms as compared to 3.0 years for those not irradiated. Minot and associates' conclusion that "irradiation has had little effect on prolonging survival" is equally applicable to other forms of therapy used in later years. Shimkin et al<sup>105</sup> found no change in survival in CML patients treated between 1910 and 1948 and in a review of the literature noted that mean survival from symptomatic onset to death ranged from 3.0 to 3.9 years. Survival figures reported more recently do not differ significantly from those reported 50 years ago.<sup>21b,40,61,75,79a,124</sup> However, in a controlled study, patients on busulfan therapy were found to live longer than those treated with splenic irradiation (Fig. 48-3).<sup>124</sup> It is conceivable that irradiation in contrast to busulfan may hasten the onset of blast crisis, thereby limiting survival.<sup>21b</sup>

Median survival of our patients to 1964 is shown in Figure 48-4. A more up-to-date analysis of 121 cases (to 1970) showed 37 months' 50% survival from time of diagnosis for all patients and 42 months for those treated with busulfan only.<sup>72a</sup> Noteworthy is the much longer survival of some patients, as illustrated in Figure 48-5.

### Causes of Death

The usual cause of death is infection or hemorrhage, often in association with blast crisis. In most instances these complications relate to the development of neutropenia or thrombocytopenia, which appears as blast crisis develops (page 1513). Other patients develop neutropenia and thrombocytopenia secondary to progressive fibrosis of the marrow.<sup>43</sup> In the terminal stages of CML, such patients may be clinically indistinguishable from those presenting with idiopathic myelofibrosis (Chapter 57). Patients in blast crisis may die as the result of formation of leukostatic lesions in the vessels of various organs,<sup>13a</sup> similar to those seen in AML (Chapter 47). A few patients die as a consequence

Fig 48-3. Survival of a series of patients with CML randomly selected to receive radiotherapy to the spleen (54 patients) or busulfan (48 patients). Arrows denote patients still alive at the time report was issued. (From Galton,<sup>32</sup> courtesy of the author and Grune & Stratton, Inc.)

Fig 48-4. Actuarial survival of 106 patients with CML treated at the University of Utah (1944-1964). Seventy-eight patients were known to be dead, 15 were living, and 13 were lost to follow-up. Median survival was 32 months, 15% lived for five years and only two patients are known to have lived more than 10 years.

Fig 48-5 Effects of intermittent therapy with busulfan on VPRC WBC, and platelet count during a 13 year course. The patient, 80 years of age, is still alive in 1975 and remains asymptomatic between courses of busulfan. Note that he has received no medication for approximately two thirds of his prolonged illness. Ph<sup>1</sup> chromosome is positive.

of marrow aplasia induced by therapy. If intermittent, rather than maintenance, therapy is employed, and if the patient is adequately observed at frequent intervals during therapy this cause of death should be quite rare. A few patients die of causes apparently unrelated to leukemia,<sup>79a</sup> but this is less common than in CLL since the course of CML is shorter and the average age of patients is lower than in CLL (Chapter 49).

#### Factors Influencing Prognosis

There are no wholly reliable means of predicting the duration of life or the time of onset of blast crisis from features present at the time of diagnosis, although platelet count<sup>75</sup> and chromosome studies (see page 1512) are helpful. In our series,<sup>75</sup> for nine patients who were initially thrombocytopenic, median survival from the time of diagnosis was less than 12 months (range 6 to 61 months); in 21 patients with a normal platelet count, median survival was 30 months (range 8 to 81); and in 39 patients with thrombocytosis, median survival exceeded 36 months (range 14 to 142). This suggests that if thrombocytosis has any prognostic implication it is a favorable rather than an unfavor-

able<sup>5</sup> sign. We could not confirm the suggestion that hepatomegaly,<sup>79a</sup> severe anemia,<sup>86</sup> or normoblasts in the blood<sup>113</sup> are poor prognostic signs and could find no significant relationship between age, duration of symptoms, degree of leukocytosis, splenomegaly, or percentage of blasts in the blood to the duration of survival from the time the diagnosis was made until death occurred. There was a suggestion that absence of basophils and/or eosinophils from blood smears was a poor prognostic sign. This may relate to the influence of the presence or absence of the Ph<sup>1</sup> chromosome defect (page 1512). A rising percentage of blood basophils<sup>28</sup> and sparse basophilic granulation<sup>39</sup> have been suggested as developments that may herald the onset of blast crisis. The rapidity of the rise in leukocyte count after completion of the first course of radiotherapy or busulfan usually has been inversely correlated with duration of survival,<sup>63,83</sup> but not always (Fig. 48-5). It may be significant that four of eight patients who were found to have increased reticulum fibers on marrow biopsy when the diagnosis was made died in blast crisis within one year.<sup>43</sup> A multifactorial scoring method for gauging the severity of disease has been suggested.<sup>89</sup> However, when applied to our

series of patients this had no better predictive value than the platelet count alone.<sup>75</sup>

For the present, the presence or absence of the Ph<sup>1</sup> chromosome appears to be the best prognostic indicator (see atypical CML, page 1512). As mentioned earlier, the absence of the Y chromosome in addition to the Ph<sup>1</sup> abnormality, 45, XO, Ph<sup>1</sup> (page 1500) may indicate a good prognosis. A summary of survival in nine such reported patients for whom survival data were available indicated that one died at 18 months and two were living less than three years from the time of diagnosis, but six of the nine lived or were living more than four years, four of these more than seven years and two more than ten years after diagnosis.<sup>36</sup>

## Therapy

BUSULFAN (MYLERAN).<sup>32, 33</sup> This appears to be the therapy of choice on the basis of cost, ease of administration, and relative freedom from toxic effects. In controlled comparative trials of busulfan in CML patients, this drug was probably superior to chlorambucil<sup>44, 101</sup> and significantly superior to cyclophosphamide<sup>63</sup> or irradiation of the spleen (Fig. 48-3).<sup>121</sup>

Busulfan is given in a single, daily oral dose of 4 mg to adults. In the event that children with CML or patients with thrombocytosis due to myelofibrosis (Chapter 57) are to be treated with busulfan, the dosage should be reduced. In the usual patient with CML the leukocyte count begins to decrease in the second or third week of therapy. If the count has not begun to decrease by the fourth week, increasing the dose to 6 mg/day may be advisable. Once the count begins to fall it decreases exponentially although the steepness of the slope varies from one patient to another (Fig. 48-6). At a dose of 4 mg/day, use of the drug can be continued with relative safety until the total leukocyte count reaches  $8.0$  to  $10.0 \times 10^9/l$ . Since the decline may continue after busulfan administration is stopped, therapy should always be interrupted when the count reaches this level to avoid inducing neutropenia. It is only rarely

that an increase in dose of busulfan above 4 mg/day may be necessary; doses greater than this are given either because of a failure of the leukocyte count to decrease by the fourth week or because the count declines but stabilizes at levels higher than  $20.0 \times 10^9/l$ . This, however, occurs very rarely. Development of apparent resistance to busulfan is quite rare (page 1511).

By the time normal or nearly normal leukocyte counts have been reached, immature neutrophils largely have disappeared from the blood and the differential count has returned to normal in most CML patients. However, in some, immature cells persist in the blood. Persistence of basophilia is common. The platelet count, if higher than normal, declines parallel with the leukocyte count (Fig. 48-5). If it falls below normal limits, therapy should be interrupted and resumed at a lower dose after the count has returned to normal. Anemia usually lessens as the leukocyte count decreases and has often disappeared by the time therapy is stopped (Fig. 48-6). The spleen almost invariably decreases in size, but a palpable spleen persists in some patients. Sternal tenderness usually disappears.

Thus, by the time the leukocyte count nears or becomes normal, most patients are asymptomatic and few signs remain. Most however, cannot be considered to be in complete remission in that a diagnosis of CML can still be made. In addition to some residual splenomegaly, basophilia, or persistent immature cells in the blood, the Ph<sup>1</sup> chromosome defect is still demonstrable in marrow and LAP usually remains low during remission.

Once drug therapy has been stopped the patient is observed at intervals of several months for a rising leukocyte count or for return of anemia or symptoms. Since patients usually become symptomatic shortly after the leukocyte count has risen to  $50.0 \times 10^9/l$  it is our practice to reinstitute therapy when that level has been reached. The duration of remission while treatment is withheld is quite variable, but averages more than six months when the leukocyte count has been reduced to less than  $10.0 \times 10^9/l$ .<sup>53</sup> Longer remis-

Fig 48.6 Changes in the blood in a series of patients with chronic myelocytic leukemia treated with busulfan. A, The rapid drop in the number of leukocytes. B, the simultaneous decrease of anemia as manifested by the rise in volume of packed red cells. In most patients the anemia was relieved completely.

sions have been observed in patients in whom low-normal or neutropenic levels were inadvertently induced. Indeed, remission persisting for as long as nine years has been reported after hypoplasia was induced with busulfan therapy followed by splenic irradiation.<sup>76</sup> Busulfan-induced hypoplasia may be quite prolonged and the possible hazards of severe neutropenia and thrombocytopenia are such that these low levels are best avoided.

The number of courses of busulfan that can be given in this intermittent manner appears limitless for all practical purposes. In Figure 48-5 the course of one of our longest surviving patients with CML is portrayed. To date he has received 17 courses during 13 years. There is a tendency for the duration of remission to decline with repeated courses of therapy,<sup>53</sup> but this is not always the case (Fig. 48-5). The uncommon, but severe idiosyncratic toxic reactions to busulfan such as pulmonary fibrosis are even more uncommon in patients treated on an intermittent rather than on a continuous basis, but hyperpigmentation of the skin is usual after multiple courses of an intermittent regimen.

Busulfan also has been used as maintenance therapy after the first remission has been induced.<sup>124</sup> When this is done, as the leukocyte count nears normal the dosage is reduced, but use of the drug is continued. Dosage is varied until a dose is found that keeps the leukocyte count approximately normal and therapy is continued indefinitely. The disadvantages of maintenance therapy as compared to intermittent therapy appear to outweigh any theoretical advantages. Patients on maintenance therapy<sup>124</sup> must be seen and have their blood examined at frequent, regular intervals for adjustment of dose as well as for detection of developing cytopenia at an early stage. Busulfan is somewhat unpredictable in producing pancytopenia and severe aplasia may develop after prolonged periods of seemingly satisfactory maintenance dosage. Most of the serious toxic effects of busulfan therapy have been reported in patients receiving maintenance therapy (Chapter 55).

Occasional patients prove resistant to busulfan or become resistant after repeated

courses in the absence of blast crisis.<sup>124</sup> In such patients other modes of therapy may prove effective (see below).

**IRRADIATION.** The spleen may be irradiated,<sup>53,124</sup> the whole body may be irradiated,<sup>1</sup> radioactive phosphorus (<sup>32</sup>P)<sup>50</sup> may be given, or extracorporeal irradiation of the blood (Chapter 55) may be employed. Splenic irradiation, usually approximately 1000 rads, not only reduces the size of the spleen, but also reduces the leukocyte count. It is thought that this is not a true abscopal effect (see Chapter 55), but, rather, is due to irradiation of immature neutrophils as they migrate through the spleen (Chapter 46). Thus, in a sense splenic irradiation and extracorporeal irradiation of the blood may be acting in a similar manner. Radioactive phosphorus localizes in marrow cells and may induce remission in CML.<sup>50,84</sup> Radiation of the spleen following chemotherapy may lead to severe marrow hypoplasia in some patients.<sup>122</sup>

**OTHER FORMS OF THERAPY.** Other forms of therapy also are effective, although none has greater proven effectiveness than busulfan.<sup>113a</sup> Chlorambucil, given in an oral daily dose of 12 mg, produces effects quite similar to those of busulfan.<sup>44,124</sup> Six-mercaptopurine<sup>57</sup> is a fairly effective agent when given as an oral dose of 2.5 mg/kg day. Actually it seems likely that any of the alkylating agents or antimetabolites will influence CML since various chemotherapeutic agents such as nitrogen mustard,<sup>34</sup> uracil mustard,<sup>31</sup> cyclophosphamide,<sup>31,63</sup> melphalan,<sup>104</sup> dibromomannitol,<sup>10</sup> hydroxyurea,<sup>65</sup> and mitomycin C<sup>56</sup> all have been shown to have some effect on the disease, as have such nonspecific cell poisons as benzol and arsenic.<sup>50,124</sup> Simply removing large numbers of blood leukocytes by leukopheresis may induce improvement.<sup>14</sup>

Resistance to busulfan is quite unusual, as noted above, but when it does occur, response to another agent such as melphalan<sup>104</sup> may still be obtained. Melphalan is administered in much the same manner as busulfan in a dose of 2 mg/day; use of the drug should be discontinued when the leukocyte count has decreased to  $8.0$  to  $10.0 \times 10^9/l$ . Hydroxy-

urea has proved to be useful,<sup>65</sup> but has the disadvantage that therapy must be continued indefinitely since the leukocyte count begins to rise almost as soon as its administration is discontinued.

## Atypical CML

There is increasing evidence that in patients who present a CML-like picture, but in whom the  $\text{Ph}^1$  chromosome is absent, prognosis is less good and the course is atypical as compared with that of patients in whom the chromosome defect is present.<sup>28,66,120</sup> Patients with  $\text{Ph}^1 (+)$  cells tend to differ from those without this defect in having higher leukocyte counts, a smaller percent of myeloblasts in the blood and marrow, greater degrees of thrombocytosis, basophilia and marrow cellularity, and lower LAP scores.<sup>28</sup> Muramidase excretion in urine tends to be increased in  $\text{Ph}^1 (-)$  patients, but not in those with  $\text{Ph}^1 (+)$ .<sup>91</sup>

Thus the presence or absence of the  $\text{Ph}^1$  chromosome appears to be of prognostic importance. Of 76 patients with a provisional diagnosis of CML referred to Roswell Park Memorial Institute between 1959 and 1967, 15 were found to have idiopathic myelofibrosis, AML, or striking degrees of eosinophilia.<sup>24</sup> The remaining 61 were considered to have CML by the usual clinical criteria; 43 were  $\text{Ph}^1 (+)$  and 18 were  $\text{Ph}^1 (-)$ . The median survival of the  $\text{Ph}^1 (+)$  patients was 40 months as compared to 8 months in the  $\text{Ph}^1 (-)$  group (Fig. 48-7). In another study, median survival was 45 months for  $\text{Ph}^1 (+)$  patients and 18 months for  $\text{Ph}^1 (-)$  patients.<sup>120</sup>

Certain patients with what appears to be best described as idiopathic myelofibrosis (Chapter 57) or with antecedent polycythemia vera (Chapter 30) develop a blood picture similar to that seen in CML subjects (page 1505). Separation of this group from atypical,  $\text{Ph}^1 (-)$  CML may be difficult.

If additional experience continues to give evidence of differences between  $\text{Ph}^1 (-)$  and  $\text{Ph}^1 (+)$  patients it may be useful to consider that they have different diseases.

Fig. 48-7. Actuarial survival of 43 patients with and 18 patients without the  $\text{Ph}^1$  chromosome (From Erdinli et al.,<sup>28</sup> courtesy of the authors and Annals of Internal Medicine)

**CML IN CHILDREN.** Leukemia in infants and children generally is acute (Chapter 47); fewer than 5% of patients with CML are children.<sup>38,58</sup> Children and infants may have  $\text{Ph}^1 (+)$  CML,<sup>52,53,81,93,120</sup> in which case the clinical features of the disease, including response to therapy, are indistinguishable from those in adults.  $\text{Ph}^1 (+)$  CML has been reported in children as young as eight months of age.<sup>7</sup> However, infants more often have an atypical form of CML in which the  $\text{Ph}^1$  defect is not present. The course is less favorable in these infants than in those with  $\text{Ph}^1 (+)$  disease and clinical features mentioned below allow the disease to be distinguished from typical CML.<sup>7,22,52,55,81,93,110,120</sup> The  $\text{Ph}^1 (-)$  form of disease has been termed *juvenile CML*, but might better be referred to as *CML in infants* since its peak incidence appears to be at age one to two years.<sup>7,30,31,33,35,50,52,81,93,110</sup> Survival from the time of diagnosis usually is less than a year and response to therapy has been poor. The spleen is less large and lymphadenopathy is more common in these infants than in those with typical CML. An erythematous, desquamating skin rash is often present. Thrombocytopenia is frequently found when the diagnosis is made and leukocyte counts tend

to be lower than in typical CML. However, low LAP levels, eosinophilia, and basophilia are found, as in the  $Ph^1$  (+) form. In all the patients studied to date an increase in the proportion of fetal hemoglobin has been present, ranging as high as 55% of the total hemoglobin.<sup>7</sup> The persistence of fetal hemoglobin and the early age of onset of CML in infants as well as its development in infant siblings<sup>55</sup> have led to speculation that the disease may be a variety of congenital leukemia<sup>7,55</sup> (Chapter 47). Whether or not CML in infants is basically the same or a different disease from  $Ph^1$  (-) CML in adults will require further study.

## Morphologic Variants of CML

A diagnosis of any form of "eosinophilic" leukemia may be questioned (see also Chapter 47). However, there are certain patients in whom very striking eosinophilia is present and in whom an otherwise fairly typical picture of CML is found. To such disease the designation *chronic eosinophilic leukemia* might be applied. In most of these patients, increased numbers of mature and immature neutrophils are found in the blood in addition to the mature and immature eosinophils. Such findings may merely represent extreme instances of the less striking increase in eosinophils present in most patients with CML (page 1502). The  $Ph^1$  chromosome has been found in patients with chronic eosinophilic leukemia.<sup>45</sup> In some of the patients in whom it has been absent<sup>42</sup> the course of the disease has resembled that described as acute eosinophilic leukemia (page 1475).

A clinical picture of CML, but with extreme elevation in the basophil count has been observed (*chronic basophilic leukemia*).<sup>27,67,82,106</sup> Joachim<sup>60</sup> was the first to emphasize that extreme basophilia could be observed in a patient with otherwise typical CML. Practically all of the leukocytes may be basophils<sup>82</sup> or the absolute number of neutrophils may also be increased.<sup>27</sup> In some of the patients, eosinophilic and basophilic granules may be present in the same cell.<sup>27</sup>

The  $Ph^1$  chromosome may<sup>106</sup> or may not<sup>82</sup> be present. The validity of considering basophilic leukemia as a distinct form of CML has been challenged.<sup>67</sup> One of our patients had as many as  $80.0 \times 10^9/l$  basophils, but had an otherwise typical course for CML, responding well to busulfan and living for 87 months after the diagnosis had been made.

*Chronic monocytic leukemia* is a term sometimes applied to the condition in which there is marked elevation of monocytes in addition to the usual leukocyte changes noted in CML.<sup>27</sup> This term also has been applied to patients with modest monocytosis, who resemble patients with preleukemic leukemia<sup>77a</sup> (page 1477). Considering the evidence that neutrophils, eosinophils, monocytes, and, by inference, basophils share a common stem cell (Chapter 2) and that CML is probably a disease of that stem cell (Chapter 46) it is not surprising to find prominent eosinophilia, basophilia, or monocytosis rather than neutrophilia in a few CML patients.

*Chronic neutrophilic leukemia* (Emil Weil's CML with polynucleated neutrophils) is a term that has been applied to a condition in which few or no immature neutrophils have been found in the blood despite marked increases in mature neutrophils.<sup>83,100</sup> Survival of patients with this type of CML usually has been reported to be as long as or longer than that of patients with typical CML. The  $Ph^1$  chromosome, reported to date only in two patients, has been absent.<sup>69,100</sup>

## "Blast" Crisis

Blast crisis is the primary cause of death in CML patients and, simply stated, it represents the conversion of CML into an AML-like picture. In recently reported series, from 56<sup>61</sup> to 60%<sup>79a</sup> of patients with CML died in blast crisis; when those dying of causes unrelated to leukemia, drug toxicity, or undocumented causes were excluded, 84% of the remaining group were found to have died in blast crisis,<sup>61</sup> as did 86% in a British series.<sup>124</sup> Analysis of our own series likewise suggested that approximately 80% of

leukemia-related deaths were attributable to blast crisis. The incidence in other series ranges from similar to much lower figures.<sup>61</sup> Part of this variation may reflect differences in criteria for diagnosis of blast crisis.

**ONSET AND MANIFESTATIONS.** The time of onset of blast crisis in relation to duration of disease is plotted in Figure 48-8. Note that during the second through the sixth year this is basically a random phenomenon. A few patients first appear in blast crisis without a preceding period of symptomatic CML, as would be implied from the random nature of this event (Fig. 48-8). The onset of blast crisis may be quite insidious and, since busulfan is of little or no benefit once it has begun, recognition of the change is important. As the crisis develops, an increased percentage of blasts and promyelocytes is found in the blood and marrow and there may be a decrease in the absolute number of mature neutrophils in the blood. A rising leukocyte count or a rising absolute number of blasts and promyelocytes in the blood without a concurrent rise in mature neutrophils strongly suggests that blast crisis is beginning.<sup>15,32</sup> As noted previously (page 1502),

Fig 48-8 Time of onset of blast crisis after diagnosis. Note that the slope of the line is best described as an exponential function.

more than 20% blasts may be found at the time of diagnosis in patients not in blast crisis whose leukocyte counts are very high. However, if the number of blasts and promyelocytes together makes up 20% of the blood leukocytes in a previously treated patient, blast crisis almost always is under way.<sup>15,61</sup> The median percentages of myeloblasts and promyelocytes were 15% and 12%, respectively, in the blood, and 25% and 15%, respectively, in marrow, in patients whom we considered to be entering blast crisis.<sup>73</sup> In some patients, unexplained fever or thrombocytopenia not attributable to drug toxicity preceded increasing numbers of blasts in the blood. Other patients may be suspected to be entering blast crisis when anemia, splenomegaly, lymphadenopathy, or hepatomegaly develops out of proportion to what would be anticipated from the height of the leukocyte count. Using combinations of these findings, death within six months has been predicted with some accuracy.<sup>61</sup> Local blastic lesions of marrow that produced bone destruction have presaged the onset of systemic blast crisis.<sup>32</sup>

If blast crisis is suspected, but not evident from examination of the blood, the marrow should be examined. If blasts and promyelocytes exceed 30% of marrow cells in a patient with less than  $100 \times 10^9$  blood leukocytes/l, then blast crisis can be diagnosed with some confidence. Additional information may be gained from direct chromosome analysis of the marrow or blood (Chapter 46).

*Extramedullary blast crisis* has been reported.<sup>19,35,87</sup> In these patients, myeloblastic tumors in locations such as the breast, meninges, or lymph nodes developed before the blood and marrow were predominantly blastic. Unless imprints are examined, incorrect diagnoses of other types of tumors such as reticulum cell sarcoma<sup>35,87</sup> may be made on sections of these blastic tumors. However, it is also possible that a reticulum cell sarcoma-like disease may complicate CML. The difficulties relating to the differentiation of myeloblastic and reticulum cell tumors have been discussed in depth, but without clear resolution.<sup>83</sup>

**CHROMOSOME ABNORMALITIES.** The majority of patients entering blast crisis are found to have chromosome abnormalities in addition to their previously demonstrated  $Ph^1$  abnormality (Chapter 46).<sup>4,15,102,120</sup> However, not all such abnormalities are indicative of the onset of blast crisis. Additional G group chromosomes, including a duplicated  $Ph^1$  chromosome, have been present for years in some patients with typical CML.<sup>102</sup> Certain others have been shown to have a duplicate  $Ph^1$  appear during blast crisis, disappear with remission, and reappear as blast crisis once again supervenes.<sup>112</sup> An attempt was made to determine which, if any, additional chromosome abnormalities might be associated with blast crisis by serial studies of a group of 27 patients, all of whom had a  $Ph^1$  defect.<sup>89</sup> The percentage of cells with chromosome defects in addition to  $Ph^1$  and the type of defect were correlated with the percentage of immature cells in the blood (Fig. 48-9A, B, and C). There was a significant and positive correlation between the percentage of hyperdiploid cells and the percentage of immature cells (Fig. 48-9A and B). However, pseudohypodiploid cells were not positively correlated with immaturity (Fig. 48-9C). Pseudohypodiploid cells are those with supranumerary chromosomes, but with deletion of other chromosomes exceeding the additions so that 45 or fewer chromosomes are present. Deletion of C group chromosomes was observed most commonly. These findings indicate that certain chromosome additions may be associated with blast crisis, but also suggest that deletion of certain chromosomes, particularly C group chromosomes, may protect the patient from developing blast crisis. In that regard the favorable prognosis associated with deletion of the Y chromosome (page 1509) is of interest.<sup>36</sup> Ob-

Fig. 48-9. Relation of chromosome abnormalities, in addition to the  $Ph^1$  abnormality, to the immaturity of blood cells in CML. A, Relation of the percentage of myeloblasts, promyelocytes, and, myelocytes to hyperdiploid metaphases, B, to pseudodiploid metaphases, and, C, to supernumerary C group chromosomes (From Pederson,<sup>89</sup> courtesy of the author and Scandinavian Journal of Haematology)

viously, more studies of specific chromosome defects, additions, and deletions are necessary before their role in blast crisis can be defined.

**COURSE** As the blast crisis deepens, neutropenia develops and bacterial infections become a problem. Thrombocytopenia occurs and hemorrhagic phenomena appear. Anemia becomes increasingly severe and transfusion may be necessary. The spleen may enlarge rapidly. Hepatomegaly and lymphadenopathy as well as infiltration of other organs may develop. Extremely large lymph nodes may be found. Fever without evident infection is common.

**DIFFERENTIATION FROM ACUTE LEUKEMIA.** Thus, all of the common features of AML develop and yet there are features that allow one to distinguish blast crisis of CML from AML even if a history of known CML is lacking. Basophilia commonly persists and may increase during blast crisis, but is uncommon in AML. Eosinophilia usually disappears. In most patients there is a greater percentage of persisting intermediate cells such as myelocytes than in AML. Spleen size is larger in patients having blast crisis than in those with AML. In 95% of our patients with AML the spleen was less than 10 cm below the costal margin when the diagnosis was made, but splenomegaly of this degree was present in 70% of patients with CML entering blast crisis.<sup>75</sup> The LAP score is not particularly helpful since it may increase in blast crisis<sup>15,102</sup> and it may be abnormally low in AML (Chapter 47). If the Ph<sup>1</sup> chromosome is present, blast crisis rather than AML is suggested strongly.

**CAUSE.** The cause of blast crisis is unknown. It has been suggested from its relative infrequency in older series<sup>59</sup> that it is more common in patients treated with busulfan than in those treated by other means. However, it is uncertain that the cause of death in earlier reported patients was examined as closely as in patients reported more recently. The frequency with which new cell lines identifiable by chromosome abnormalities appear suggests that blast crisis represents clonal evolution of a more malignant cell

line.<sup>15,102,111,112</sup> This suggestion gains additional support from reports of patients in whom new chromosome abnormalities appeared with blast crisis, disappeared during an induced remission, and reappeared with return of blast crisis.<sup>11,20,37,90,112</sup> The evolution of blast crisis in apparently single, extramedullary sites<sup>19,35,87</sup> or in isolated areas of marrow<sup>32</sup> is compatible with a clonal evolution. However, explanations other than clonal evolution of a malignant cell line can be found for chromosomal change in leukemia<sup>102</sup> (see Chapter 46).

The morphologic characteristics of the immature cells in blast crisis of CML generally has been compatible with a myeloblastic evolution. However, on occasion, an *erythroblastic evolution*, reminiscent of DiGuglielmo's syndrome (Chapter 47), has been observed.<sup>112</sup> We also have observed patients in whom the blastic evolution was evidenced by immature cells predominantly of the morphologic type best described as monocytic or myelomonocytic (Chapter 47). This type of evolution (erythroblastic or monocytic) is compatible with our current concept of the nature of CML; namely, it is a disease affecting stem cells potentially pluripotent for mature neutrophilic, monocytic, and erythrocytic as well as eosinophilic and basophilic cells (Chapter 46).

**THERAPY.** Therapy of blast crisis is no more satisfactory than that of AML (Chapter 47) and perhaps even less so. Combined chemotherapy with 6-MP, methotrexate, vincristine, and prednisone induced a smaller number of remissions in patients with blast crisis of CML than in those with AML.<sup>30</sup> In general the same drugs that are effective in AML subjects have induced occasional remissions in patients with blast crisis of CML. We observed five complete remissions in 11 patients treated with combined 6-mercaptopurine and cytosine arabinoside, but these were of short duration, averaging only five months. Remission also has been reported in nine of 30 patients treated with vincristine and prednisone, agents which are rarely, if ever, of benefit in AML, although useful in ALL.<sup>15</sup>
